An exploratory operation was decided upon and a vertical incision about three and a half inches in length was made in the right iliac region, where an area of dulness was outlined. As soon as the peritoneal cavity was opened a gray turbid fluid containing shreds of necrotic tissue and fibrin escaped. The omentum was much reddened and studded with white areas, pin-head to pea size, which were not raised above the surface. The intestines and omentum were matted together by fibrinous adhesions, and walled-off numerous pockets containing the same turbid gray fluid above described were found. A large gauze drain was inserted and antiseptic dressings applied. The patient died soon after the operation. The diagnosis of pancreatitis was confirmed by the postmortem findings.

Autopsy.—The postmortem examination showed the following: A man, well nourished, neck thick, chest full, abdomen distended, rigor mortis well marked. In the right flank is a recent incision about four inches long, from which bloody fluid exudes. Slight adhesions exist between the abdominal wall and the omentum. The peritoneum is rough with fibrinous masses adherent to it. In the omental fat, and to a lesser extent the abdominal wall, are irregular grayish white patches varying from minute to larger coalesced areas. Those in the abdominal wall are found only near the peritoneum. The abdominal cavity contains a turbid grayish red fluid. The pleural cavities are empty. The pericardial cavity is empty and its surface smooth. The tongue, pharynx, trachea and esophagus show no changes. The thyroid is small. The lungs crepitate throughout and their lower lobes contain much frothy blood. The peribronchial glands are enlarged and markedly calcareous. The heart weighs 400 grams and on its anterior surface is an irregular white patch, at the lower border of which there is calcareous material. It contains fluid blood and a few large clots in the right side. The tricuspid orifice admits six fingers. The right auricle is large. The endocardium is normal with the exception of a few areas of thickening in the mitral valves. The mitral admits five finger tips. There are several aberrant chordæ tendinæ in the left ventricle. The heart muscle is smooth and flabby, reddish yellow in color, and has a boiled appearance. The coronary arteries are tortuous and show a few yellow areas of thickening.

The spleen weighs 220 grams. Its surface is covered with a fibrinous exudate. It is soft, the pulp is swollen and there is little connective tissue. The kidneys together weigh 380 grams. The capsule is not adherent. The kidney substance is soft, the cortex swollen and the cortical markings indistinct. The urethra, bladder, ureters and testicles are negative. The liver weighs 2100 grams, and is adherent to the diaphragm which is pushed up to the third rib on the right side and the fourth on the left. The liver substance cuts readily, the surface being rather granular, of a uniform red color, with small areas of a deeper red. The gall bladder is distended with thick, viscid, dark green bile. The mucous membrane is smooth and velvety.

A large cavity is found in the region of the pancreas. It contains fluid of a dirty yellowish gray color, mixed with shreds of disintegrated material. The fluid has escaped into the abdominal cavity through a rupture whose margins are necrotic, and of a bluish gray color. Stretching across the cavity are remnants of the pancreas, much softened. The entire pancreas is involved in the cavity and contents. The fat tissue around the pancreas contains numerous white areas like those found in the omentum. The coils of small intestine are slightly adherent to each other by fibrinous masses. Large clots of fibrin are found in the posterior part of the abdomen.

Bacteriologic examination.—There was found in the blood from the heart, and in the spleen, liver, kidney, and in the necrotic areas in the subperitoneal fat, a bacillus corresponding to the cultural and other characteristics of the bacillus coli communis.

Anatomic diagnosis.—Gangrene of the pancreas; disseminated fat necrosis of omentum and subperitoneal fat; diffuse sero-fibrinous peritonitis; acute degeneration of the kidneys; cirrhosis of the liver; dilatation of the heart and degeneration of the myocardium; sclerosis of the coronary arteries; calcareous and caseous areas in the peribronchial lymph glands.

A histologic examination of the areas of fat necrosis showed practically the same conditions as those of Case 1.

The literature of pancreatitis has been so recently summarized by Simon Flexner¹ that only a few salient points will be mentioned here. According to Fitz,² fat necrosis in the peritoneal cavity is infrequent in the suppurative and relatively frequent in the hemorrhagic and gangrenous forms of pancreatitis.

The first attempt to prove the relation between the pancreas and areas of fat necrosis was made by Langerhans.³ From his studies he concluded that fat necrosis was due to a decomposition of the fat molecule and a combination of the fatty acid with calcium salts present in the blood, to form a calcium soap. By injecting fresh pancreas pulp into the peritoneal fat tissue of a rabbit he produced a local inflammation with areas of fat necrosis.

Experiments by Dettmer, Hildebrand, Korte and Williams show, as previously asserted by Senn: 1, That the secretion of the pancreas can enter the peritoneal cavity without causing inflammation; 2, in a certain number of cases the free sterile pancreas or its secretion causes areas of necrosis; 3, the element of infection plays an insignificant part.

Dettmer found that pure trypsin caused a sero-hemorrhagic exudate into the peritoneal cavity, but did not set up fat necrosis. Hence it was concluded that in all probability the fat-splitting ferment was the active agent.

Flexner experimented on cats and dogs, ligating the veins coming from the pancreas, or one-half of the pancreas itself. By both methods he caused fat necrosis. The conclusions of Flexner are: 1, In the peritoneal fat necrosis the fat-splitting ferment is demonstrable at certain stages of the pathologic process; 2, it is most abundant in the early period and may entirely disappear later; 3, though it can not be said positively that steapsin is the direct cause of the necrosis of tissue, such an assumption is rendered most probable by its constant occurrence in the diseased areas, its absence from healthy fat, and the nature of the pathologic changes; 4, the escape of the pancreatic secretion into the peri- and para-pancreatic tissues is the origin of the necrosis, and this escape is facilitated chiefly by lesions of the pancreas and by disturbances in its circulation. Fat necrosis occurring from other causes is not excluded. It is quite probable, Flexner thinks, that some are due to microbic agents.

Accidental findings in the postmortems show that mild cases of fat necrosis occur which do not cause death. Balser,⁴ who first described fat necrosis, found it present in five out of twenty-five postmortem examinations. The areas were present in the intra-acinous tissue of the pancreas or the adjacent fat tissue. Since that time they have been found in many instances in which a gross disease of the pancreas was wanting. In such cases the areas were usually small. In Balser's cases the cause of death varied greatly, as is seen from the following enumeration: 1, Male, 52 years old, much emaciated, phthisis pulmonalis; 2, male, 42 years old, general anasarca, aortic regurgitation and stenosis; 3, male, 61 years old, carcinoma of stomach, peritoneum and omentum; 4, male, 48.

years old, much emaciated, carcinoma of stomach; 5, male, 60 years old, emaciated, cirrhosis of liver.

The etiology of pancreatitis is not definitely known. Syphilis and an excessive use of alcohol are mentioned by most writers as the chief factors. Eichorst, Koenig, Senn, Strümpell, Loomis, Osler, Ziemssen and Eulenburg speak of pancreatitis as sometimes following acute tuberculosis, typhoid, pyemia, septicemia and parotitis. The chief symptoms mentioned by all are: Sudden onset, with violent colicky pains in the epigastrium, vomiting, early collapse, constipation or diarrhea, with frequently fat in the stools and sugar in the urine.

In the cases reported by the writer there was a history of the excessive use of alcoholics in one and of alcoholism and syphilis in the other. Both cases had a sudden onset with severe colicky pains, by one referred to the epigastrium, by the other principally in the iliac fossæ. The first case had diarrhea and later involuntary bowel movements. The second had obstinate constipation. Both vomited excessively.

The surgery of pancreatitis is not definite. Senn⁵ speaks of making a lumbar incision for drainage after making an abdominal incision. Koenig, however, thinks a diagnosis is seldom made before the rupture of the pancreas into the free abdominal cavity has taken place. Eichorst claims a positive diagnosis is impossible.

A CASE OF CONGENITAL MALFORMATION OF THE HEART.

BY ALFRED H. SCOFIELD, A.M., M.D.,
RYAN, IOWA.

Mrs. B., was confined May 5, 1898, at 3 A.M. Ineffe-
fectual pains had persisted at intervals since 2 A.M.,
May 2, with partial escape of amniotic fluid at that
time. It was not, however, till the evening of the 4th
that the uterine contractions became regular and vig-
orous. The case was a brow presentation. The head
was considerably deformed by pressure and a couple
of minutes elapsed before respiration was established.
The child's cries were weak and hoarse. It was
remarked that the action of the heart was unusually
vigorous. After an hour the child was left in appar-
ently good condition.

At 5 A.M. the writer was summoned with the report
that after a feeble attempt at nursing the child had
died in the mother's arms while she was sleeping.

An autopsy made a few hours later showed the
lungs only partially distended. The heart was normal
in appearance, filled with fluid blood. There was a
partial defect in the inter-ventricular septum consisting
of an opening 5 mm. in diameter at the top of the
septum and so situated that a probe introduced into
the aorta, entered much more readily into the right
ventricle than into the left. In other respects the
heart was normal.

The conclusion was arrived at that incomplete aera-
tion of the blood was the cause of death and that the
exaggerated heart action was an effort at compensation.

CHRONIC SUPPURATIVE ETHMOIDITIS.

BY LEWIS S. SOMERS, M.D.

PHILADELPHIA, PA.

Both acute and chronic inflammation of the ethmoid
cells occur in a much larger proportion of cases than
is generally supposed, and from the intimate relation
of these sinuses with the cranial cavity and accessory
nasal chambers irreparable damage may result in a
comparatively short time from the onset of the affec-
tion. Either the anterior or posterior ethmoid
cells may be the seat of a suppurating process, alone
or in conjunction with the maxillary antrum, frontal
sinus or sphenoidal cells and the morbid changes may
be acute or chronic, the affection commencing as a
simple congestion of the mucous lining and disap-
pearing in a short time, or pus may form, with serious
results to the bony tissue and adjacent parts. The
posterior group of cells with which we are concerned
in this paper are not affected as frequently as those
situated anteriorly, and therefore have not been
studied to the same extent as have diseases of the
latter region.

Acute or chronic rhinitis is probably the chief etio-
logic factor in a considerable number of cases, the
inflammation spreading from the nasal mucous mem-
brane to the lining of the cells and from the intimate
attachment of the mucous membrane to the bone,
changes in the latter structure taking place quite
early, while suppuration of the adjoining sinuses may
communicate to the ethmoid region, this being seen
especially in suppurating frontal sinusitis and occa-
sionally from the sphenoid cells and antrum of High-
more. Retention of secretions from closure of the
ethmoid opening into the nasal cavity, may result
from simple hyperplasia of the middle turbinal or
from a polyp obstructing the outlet, but in not a few
cases these are effects of the ethmoid inflammation
and not causes. Other factors, such as irritation
resulting from the retention of a foreign body in the
nasal chamber, may be prominent in the etiology and
general affections, or dyscrasias may produce local
changes in this region, among these syphilis espe-
cially in the tertiary form, being the most common,
while tuberculosis has been credited as the cause in a
small number of cases.

When the ethmoid cells adjacent to the frontal
sinus are affected, the patient may complain of a dull
pain at the root of the nose and a unilateral purulent
discharge from the nasal cavity, and when suppu-
ration is confined to the posterior cells these symptoms
may also be present, but the case often requires care-
ful study before the nature of the affection is fully
comprehended. Usually the patient will complain
only of the symptom-complex forming the clinical
picture of the ordinary form of chronic hypertrophic
naso-pharyngitis and the nature of the affection
becomes apparent only after careful investigation of
the nasal chambers, but in the acute cases definite
symptoms are present, that readily allow of prompt
recognition. In the chronic affection with which
we are concerned there may be no subjective symp-
toms of sufficient importance to specially attract the
attention of the patient, and the recognition of the
suppurative ethmoiditis must be based on the objec-
tive signs alone.

The affection may be either unilateral or bilateral,
the former being most frequent except in specific
cases where the entire bony structures of the nose are

destroyed. Examination of the affected nasal cavity will reveal the presence of pus, bright yellow in color before the bone becomes necrosed and later becoming thick and caseous as the solid structures are involved. The turbinal bones are seen to be hypertrophied, the middle especially being much enlarged and occasionally it is cleft near the median line. Mucous polypi are frequently present and the septum may be ulcerated from pressure by the hypertrophied middle turbinate. Much information can be gained by cleansing the nasal chamber and observing the location from which the pus comes. If the cavity be well illuminated and the head of the patient placed forward and toward the unaffected side, we may see a thin stream of purulent matter escaping over the middle turbinate. Posterior rhinoscopy reveals the middle turbinal to be much enlarged and frequently covered with accumulated pus which the patient has found impossible to dislodge.

Anosmia is a variable symptom and may or may not be present, it being difficult to obtain an accurate statement as to the presence or absence of the olfactory function, for should the duration of the affection be over a considerable period of time, the disgusting odor from the necrosed bone will prevent the patient appreciating other odors. General symptoms are observed in a few cases, the temperature showing a slight elevation at various times and there may be occasional rigors, but little information as to the nature of the affection can be gained from the general symptoms: more frequently, however, we find the patient complaining of loss of appetite and morning nausea, the result of swallowing the purulent secretions which escape into the pharynx during sleep. The general health may be seriously affected in other cases from septic absorption, the symptoms of septicemia being marked, as seen in other conditions, while in rare instances no indications of suppuration are present at any time during the course of the affection, the ethmoid involvement only being discovered accidentally as the following case well illustrates, no acute symptoms or rapid onset of the disease being noticed by the patient.

F. A., age 23 years, hat-presser by occupation, was first seen May 25, 1897, complaining of bilateral nasal obstruction; accompanying this was the discharge at frequent intervals and from both nasal chambers of fetid, membranous masses, and at all times the odor emanating from the nasal cavities was noticeable to those around him although he could not perceive it. At irregular intervals there was slight epistaxis and a muco-purulent naso-pharyngeal discharge, especially marked in the morning upon arising. The nose besides being obstructed, felt dry. This condition had existed for three years in a minor degree, but the fetor and obstruction had increased to a considerable extent during the past few months. Previous history was negative, no evidence of syphilis and no similar nasal trouble having existed in any of the family and he always having been exceptionally robust and healthy.

The left middle turbinal was much hypertrophied and almost touched the septum, especially at its posterior two-thirds; it bled freely on being touched with a probe and, in part, the epithelium was macerated, while other portions were denuded of their mucous membrane. Filling up the entire posterior half of the left nasal chamber was a black mass, resembling false membrane; removal of portions of this revealed

the presence of a bed of pus beneath, the odor, on the least disturbance of the membrane, being almost unbearable. When all the secretions and membrane had been removed, the middle turbinal bone was seen to be denuded of its mucous covering at various points. The presence of dead bone was ascertained with the probe, and from the various necrosed areas in the turbinal, pus, green and fetid in color, was seen to exude. The inferior turbinal was moderately hypertrophied and inflamed, with loss in part of the surface epithelium, and on the septum directly opposite the middle turbinal was an ulcer due to necrosis of the mucous membrane covering the vomer. The right nasal chamber presented practically the same appearance as seen on the left, except that the middle turbinal was fissured, the probe on entering the cleft grating against dead bone. The turbinal on this side was more enlarged than on the left and was attached to the septum by a bony synechia. This was complete above the lower border of the middle turbinal, with a space below through which the air passed, and corresponded to the inferior nasal fossa. The pathologic process was more marked on the right, the patient complaining the most of obstruction and the presence of the membrane on this side, and on the left the membrane is discharged in small pieces after violent efforts, while on the right it frequently comes away in a single cast of this portion of the naris. Granulations were present over the necrosed areas in both middle turbinals.

The pharynx was sclerotic. Post-rhinoscopic examination showed a patulous inferior nasal fossa on both sides. The middle turbinals were much diseased, but the appearance presented nothing more than could be learned from an anterior view. The case was seen for treatment every third day for two months when he considered himself well enough to discontinue treatment and I have not seen him since. General symptoms were not well marked, occasional headache only of the frontal and occipital regions being noticed, and while there was a loss of a few pounds in weight, he presented no marked constitutional evidences of the severe local affection. The treatment consisted in removing the pus and debris with an alkaline, antiseptic spray and then what remained was removed with a probe and dull curette; this was followed by thorough spraying with a peroxid of hydrogen solution, which not only cleansed the parts but controlled the bleeding and nosophen in full strength was insufflated over all the diseased area. Previous to this the patient was informed that he could only obtain permanent relief through operative interference under a general anesthetic; this was refused, so the parts were anesthetised with a 4 per cent. solution of cocaine and necrosed bone and debris removed as far as possible with a sharp nasal curette, the parts then being covered with nosophen as previously mentioned; this was repeated at intervals until the membrane practically ceased to form and the nasal condition was decidedly improved. At the end of two months' treatment there was absolutely no odor, the septal mucous membrane was normal, the middle turbinals on both sides were greatly reduced in size allowing free breathing space, the pus and membrane had entirely disappeared and there was no post-nasal discharge. Treatment consisted essentially in removing all diseased tissue, obtaining free drainage and maintaining asepsis as far as possible.

Frequently perfect casts of the posterior half of

the nasal cavity were removed by forcibly blowing the nose: one of these casts on macroscopic examination measured one and three-quarters inches in length, by three-quarters of an inch from above downward; it was one-eighth of an inch in thickness, a deep grayish-black in color, with here and there over the external surface patches of pus and blood. Through the center of the cast was a perforation extending from before backward, approximately measuring one-quarter of an inch in diameter and through this central cavity respiration to a limited extent was carried on. The cast was thick and resembled moist papier maché to the touch and had a most intense odor; when dried it became shriveled and brittle and tough like leather. Portions of the membrane were placed under the microscope and pus, red blood cells, amorphous debris, cholesterol crystals, small particles of necrosed bone, bacilli and cocci were found forming the mass. The larger portion of the cast was composed of amorphous material and pus cells, the red blood cells being but few in number, while cholesterol crystals were found in considerable amounts. No researches were made as to differentiating the micro-organisms, except that the staphylococcus and streptococcus were found to predominate.

The dangers incident to suppuration of the posterior ethmoid cells increase as treatment is delayed or not thoroughly carried out. Caries and necrosis of the walls with extension of the inflammation to the fronto-ethmoidal cells and involvement of the orbit has occurred, while the cranial cavity may become involved and fatal meningitis result. The progress of this form of ethmoid disease is slow, often extending over months, and in this case several years elapsed before it was recognised. Although the course may be much shortened by prompt and radical treatment, yet a certain degree of caution must be observed in operating on account of the unfavorable location of the posterior ethmoid region.

3554 North Broad Street.

HAY FEVER.

BY W. H. WEAVER, M.D.

PROFESSOR OF RHINOLOGY AND LARYNGOLOGY IN THE CHICAGO EYE,
EAR, NOSE AND THROAT COLLEGE.
CHICAGO, ILL.

My chief purpose in reviewing the subject of hay fever is to define more clearly, if possible, the philosophy of its treatment by internal medication in addition to the recognized surgical measures which should be adopted. The majority of patients have received only local nasal treatments, which have given variable success, no effort being made at internal medication. My experience in the past three seasons has convinced me that one of the most important factors in the pathology of the disease is the uric acid diathesis, or rather a condition of temporary uricacidemia. Uric acid, with other toxic matters which are retained with it in the blood, is certainly a violent irritant to the tender and irritable tissues in hay fever as well as in other diseased states; and when its importance is fully recognized it will be much easier to relieve the sufferer.

The nervous symptoms are reflex, from the local irritation of the sensitive area, reflex through the ganglionic and cerebro-spinal nerve connections. The ganglionic system presides over the functions of secretion and excretion, nutrition and circulation, as well as involuntary motion. These ganglia, composing the

sympathetic system, also give warning through their intricate network of connecting nerve fibers, of abnormal conditions. The warning may be sent to the same organ in which the irregularity occurs, or to other organs. This will explain the production of various symptoms occurring in hay fever. The local irritation of Meckel's ganglion is reflected through its various branches, producing, in time, the symptoms of rose cold or hay fever—through the descending palatine branches, causing itching of the mouth, most often referred to the point where the nerve emerges from the posterior palatine foramen, as well as through the naso-palatine nerve at the anterior palatine foramen, behind the incisor teeth, through the internal nasal branches, causing engorgement of the erectile tissue with the profuse discharge of mucus through the upper posterior branches, the pharyngeal and a few through the Vidian nerve to the mouth of the Eustachian tube and pharynx, producing the itching of the ears and throat, through the branches to the ophthalmic ganglion, producing the intense eye symptoms observed in many cases, and through the branches of the cervical sympathetic ganglion producing hay asthma and dyspnea. In the milder cases the symptoms of dyspnea and asthma are often absent.

In the study of the etiology of this disease we find these two factors to be taken into consideration: first, irritation; and second, a sensitive area of membrane.

The sources from which come this intense irritation, producing the sensibility of the nasal mucous membrane, may be classed as external and internal. External irritants are dust, pollen of certain plants, most of which bloom during the latter part of August, septic germs and corrosive and irritating discharges and polypi. As internal irritants we have, as first in importance, toxic conditions of the blood, especially an excess of uric acid and the products of incomplete metabolism, or retained waste matters floating in the blood. This excess may be due to a too rapid supply of uric acid from a rich diet or faulty digestion, or to torpidity of the excretory organs, probably to both.

The heat of the summer with its relaxing effects and perspiration and consequent chilling of the surface, interfering with the proper action of both the skin and kidneys, the excessive amount of water drunk and consequent delay of digestion, producing gastro-intestinal catarrh, all have a decided effect in loading the blood with impurities and lowering the resistance to the action of irritants. As a second source of internal irritation may be mentioned reflex action from the sexual apparatus, due to the correlated action of erectile tissues, as so ably presented by Dr. J. N. Mackenzie. The varying character of the disease in different cases is due to the fact that these different factors vary in their pathogenic importance; now the local nasal condition is the cause alone, now the rheumatic diathesis, now the reflex influences from tumors or other causes, and possibly a neurotic element in some cases, and finally a combination of some or all of these elements.

These internal irritants, or toxic elements of the blood, must be expelled if success is attained in the cure of every case. This may be done by an eliminative form of treatment including alkaline and stimulating diuretics; a 0.65 gram dose of salicylate of soda with each meal often gives complete relief. A vapor bath may be given two or three times weekly. Light woollen underclothing must be worn to protect the skin from too rapid evaporation and chilling of

the surface. Diet should be plain and not stimulating restricted to those articles which do not produce much uric acid, sugar and meats sparingly. In many of the milder cases this medical treatment is sufficient to give immediate relief, but in order to make the cure certain and permanent in all cases the second factor in the etiology, the sensitive mucous membrane, must receive attention.

When the symptoms appear to be confined to the eyes and anterior portion of the nose the source of the irritation will usually be found in the sensitive area of Sajous, which he has described as the region of the anterior extremity of the middle turbinated bodies or the middle turbinated bodies themselves. There will be found a hypertrophy of one or both of these bodies so that there is close contact with the septum or the upper portion of the lower body. This latter form of contact is often overlooked but may be discovered by passing a bent probe between the middle and lower bodies. Cocain may reduce the engorgement somewhat, and will enable the operator to locate the hypertrophy, which will usually be granular or corrugated in appearance. Or cocain may fail to reduce it and the body will remain large and red. When this condition is found no treatment will take the place of the snare, and sufficient tissue should be removed to give free surfaces, no contact and good drainage. There will usually be found accompanying this condition of the middle turbinated bodies a soft hypertrophic area on the septum, just anterior to the previously mentioned point of contact of the turbinated body. This should be cauterized deeply. This particular hypertrophy is often neglected and will continue to be a source of irritation if not reduced. It has been said that these hypertrophies of the septum should not be cauterized, but I have never failed to get good results from the procedure.

When the symptoms are severe and involve the throat and ears, and are accompanied with asthma, then probably the source of greatest irritation lies in what Dr. J. N. Mackenzie has described as the posterior ends of the lower turbinated bodies and the surface of the septum opposite. This is called "Mackenzie's sensitive area." The posterior end of the lower turbinated body is usually hypertrophied and may be called the sensitive hypertrophy. It may be seen in most cases by posterior rhinoscopy, having a granular or corrugated appearance, large and pale. The shortest branches from Meckel's ganglion supply this area, and stimulation or irritation being reflected through any of the branches and connections will produce the symptoms of hay fever.

The most pronounced benefit will be given by treatment of these sensitive hypertrophies. Often the symptoms are immediately relieved when these areas are properly treated. The most appropriate treatment for this hypertrophy is also the snare, after complete anesthesia with cocain. The operation should occupy a few minutes, so that there will be but little hemorrhage. When the snare can not be used I cauterize in one of two ways, preferably by the galvano-cautery, using an electrode which I have had made with a loop to hook over the projecting hypertrophic tissue. Or, what has given me the very best results, is the use of chromic acid on the end of a bent probe, so as to reach over the surface of the posterior end of the body, which can not be done with a straight probe. Care must be taken not to touch the tissues near the Eustachian orifice. This treatment

will be followed by considerable reaction with discharge, but when the healing process is complete the hypertrophy, as well as the irritability, will be reduced. Some of the most intractable cases of asthma are cured by removal or cauterization of these hypertrophies, removal of the polypi or other intranasal irregularities, which irritate this sensitive area. Also, some of the worst symptoms of chronic rhinitis are quickly relieved when treatment begins at this point. The chronic alternate congestion of the turbinals, as well as the profuse discharges, subside. The bodies are then left to their proper sympathetic influences, which regulate the secretion of fluid and other functions of the nasal mucous membrane.

It has been shown that when simple hypertrophy is the cause of nasal obstruction and the bodies are deeply cauterized their contraction is often so great that inspired air is not properly warmed and moistened, the throat becomes dry and the patient may be in a worse condition than before. In catarrhal areas not truly hypertrophic, deep and destructive cauterization for the purpose of button-holing the membrane to the bone, to prevent erection of the turbinated tissue, is wrong in theory, never necessary and does actual harm. Diagnosis must be made by aid of cocain, which reduces the engorgement and at the same time brings out clearly the flabby, corrugated, true hypertrophy, which alone must be treated.

In the treatment of these hypertrophies, all obstructions, such as polypi, deflections, ledges, spurs and anterior hypertrophies, should be removed in order to gain easy access to the post-nasal regions, and to make the nasal cavities conform to the ideal nose at least in point of drainage and ventilation. For the cure of hay fever the treatment of these most sensitive areas and other very radical departures from the normal should be completed before the beginning of the hay fever season, then, during the season, medical treatment and other measures rigidly carried out will insure success.

Internal medication is not needed in every case, as local treatment of the nasal irregularities is often sufficient, but when it is required it will assist greatly in the relief of the irritability of the nose and general symptoms. The great majority of cases of hay fever are certainly easily curable if tact and patience are employed with the treatment.

I have omitted the discussion of a neurotic condition peculiar to this disease for the reasons that when a frost occurs or when the patient is transported to a place where the atmosphere is free from all irritating qualities which cause the symptoms, all the phenomena of the disease cease almost immediately; also, when the blood is freed from impurities, uric acid and other waste matters, by the treatment above described, the symptoms are quite, if not entirely, controlled; also, that neurotic remedies have not the slightest perceptible effect on the progress of the disease.

Dr. J. O. Roe, in an article on "Hay Fever" (*New York Medical Journal*, Sept. 3, 1887), has ably described the proper treatment of the intra-nasal conditions, and closes his article with the following conclusion: "That by carefully correcting all abnormal conditions found in the nasal or other portions of the respiratory passages, and the use of such systemic medication as may be required to remove any associated or consequent general derangement, we need not fail to cure hay fever."

Dr. Roe, however, gave no outline for internal medication, or what particular conditions were to be remedied by it. He reported thirty-six cures out of a total of forty-four cases by local treatment. From the nature of the disease it will be admitted that a permanent cure must come from treatment and relief of the excessively sensitive nasal mucous membrane and that cure will be hastened and the patient made comfortable during the treatment by internal medication. I believe that every case is curable by the combined treatment.

I report a few cases, with what seemed to be the most appropriate treatment for each case:

Case 1.—Miss I. M., aged 22, has had hay fever for the past three years. Her treatment consisted of chromic acid cauterization of the posterior ends of the inferior turbinated bodies and trichloroacetic acid applications to the anterior extremities of the middle turbinated bodies, done during the season, with complete cure.

Case 2.—Mrs. N. H. has had a most severe case of hay fever extending over a period of twenty years. The nasal mucous membrane was greatly hypertrophied and very sensitive. I removed and cauterized the hypertrophies until I could find no more to treat. She still had some hay fever irritation but was greatly improved. Doses of 0.65 gram of salicylate of soda with each meal completed the cure for last season.

Case 3.—Mr. H. W., aged 39, with a rheumatic diathesis, a year ago developed hay fever, but has had no recent treatment for abnormal nasal conditions. During the past season the symptoms of hay fever were kept under entire control by salicylate of soda and alkalin diuretics, but if they were discontinued for a few days the symptoms would return.

Failure to cure undoubtedly arises from placing our reliance in a single line of treatment, to the exclusion of other supplementary measures, or inefficient intra-nasal treatment. There are hardly two cases alike and each should be studied for the best method of relief.

92 State Street.

PHYSICAL DEFECTS IN PUPILS.

Read at the Annual Meeting of the Associated Minnesota School Boards, held at St. Paul, Dec. 30, 1897.

BY FRANK ALLPORT, M.D.

PROFESSOR OF OPHTHALMOLOGY, CHICAGO POLICLINIC, ETC.
CHICAGO, ILL.*

I will take up that phase of the subject which deals with the problem of how best to preserve the eyesight of school children, a theme which is pregnant with importance. The prosecution of this subject opens up a wide field, involving not only those elements or conditions, which primarily and particularly bear upon ocular hygiene, such as print, lighting, etc., but also upon those circumstances obtaining during the school life of the child, which can either directly or indirectly affect the preservation or degeneration of his eyesight. Such consideration will lead us into a discussion of architecture, buildings, location, window space, lighting (natural and artificial), seats, desks, walls, blackboards, maps, charts, paper, slates, printed matter, writing, etc.

The importance of this topic may be imagined, when we consider that James H. Blodgett, in 1890, estimated that over fourteen million children were in attendance in the different schools and colleges of the United States. When we consider that the average of children possessing defective eyes in our schools is estimated to be from 25 to 30 per cent, it will be seen that at least three and one-half million children attending school in the United States possess defective eyes. It will thus be seen that the magnitude

and importance of the problem, as to how best to subserve the ocular interests of this great number of school children, is enormous.

The consideration of defective eyes as a consequence of school life, was first publicly noticed by A. G. Beer, who, in 1890, published a treatise on "Healthy and Weak Eyes." He was followed, in his investigations, by Ware, Szokalski, Shurmayer, Jaeger, Reuta, Reck, Alexander, Gaertner, Cohn, Risley, Randall, and others. I, myself, have superintended the examination of over 10,000 pupils, in the Minneapolis public schools, the past year, by the method which I proposed in 1895. The Minneapolis tests have shown an average of 32 per cent. of children possessing defective eyesight. In all, between two and three hundred thousand children have been examined, according to different methods, in the schools of the world, and the percentages arrived at in Minneapolis are about the same as those obtained in other examinations, although in some of the German universities, where bad print, studious habits and hereditary influences are prominent, from 50 to 75 per cent. of ocularly defective students are not infrequently observed. The objective point obtained by these researches is the inevitable truth that myopia or short sightedness, or an elongated, softened eyeball, is the principal pathologic condition of the eye, induced in children by study, and that the more imperfect the conditions under which the child studies, the more surely, steadily and rapidly will myopia develop.

The frequency of myopia in students has led some observers to believe it to be a natural evolution of tissue, incident and similar to the natural expansion and enlargement in other tissues of the body. These deductions are inaccurate and can not be substantiated. Such superficial observers evidently forget that the natural evolution to which they refer is practically a class evolution, and is found principally among students, or at least among those who attend school and use their eyes to a greater or less degree for the purpose of acquiring an education. Evolution of this kind does not exist to any great extent amongst those whose occupations are essentially separated from those of an educational nature. In other words, ocular examinations among uneducated farmers, Indians and others, who practically never read or study, show the myopic eye to be conspicuously infrequent. People of such classes undergo evolution of tissue quite as much, and perhaps more so than the student, yet it is in the latter class that the elongated, softened, myopic eye plays such an important role. Myopia, therefore, while not confined to students, is especially frequent in them, and must inevitably be classed as a pathologic condition, and not a physiologic evolution, and is, unquestionably, principally caused by confinement and the more or less injudicious use of the visual organs. In other words, a myopic eye is a diseased eye, and should always be regarded and treated as such. The frequency of myopia has also led some observers to believe that a slightly myopic eye is the normal eye. This claim can not be substantiated, for a great number of observations have shown that the natural condition in infancy and early childhood is either emmetropia or hypermetropia.

Myopia is rarely seen before school life commences, some observers even claiming its non-existence in very early childhood. Its frequency steadily increases during school life, from class to class, and from room to room, and hypermetropia diminishes in proportion

* Formerly of Minneapolis, Minn.

to the advance of myopia. Some authorities believe that myopia is not hereditary, only the tendency to myopia, and that this inherited tendency is augmented by certain abnormal and inherited shapes of the skull, socket, etc. While the infrequency of actual inherited myopia must be admitted, the statement that it is an absolutely uninherited condition is too sweeping, and the observation of whole families of myopic parents and children, which come under notice, from time to time, must convince an unbiased observer that myopia is a condition possible of transmission from one generation to another. If school life, with all its incident evils is capable of producing myopia, then it must be equally true that a mitigation or a removal of these evils, must be capable of decreasing the number of myopic children. That this is true, is amply proven by statistics gathered in this country and in Europe, where the proper correction of myopia by glasses, the erecting of more properly and abundantly lighted schools, the improving of desks and seats, the changing of curriculums of study, etc., have unquestionably diminished the percentage of myopes in a given community. In investigating this subject we are, therefore, not chasing an interesting scientific fact, but we are endeavoring to arrive at some truthful deductions which will enable us to improve the ocular conditions of the coming generation.

The public schools of the United States are the crowning glory of this country. When we glance back at our own childhood days, and remember the hot, stuffy rooms, with their meager and poorly directed illumination, and the other unhealthy and unpleasant conditions and methods of obtaining a common school education, and then pass through some of the beautiful school buildings of our cities with their cheerful and pleasant surroundings, their teachers and general facilities, we can not but see that the public school system has improved and is improving steadily, and that educators are eager to accept suggestions that will still further improve this system and render it as near perfect as possible. While I am well aware that the curriculums of study at present in vogue in our public schools are much less severe than those which formerly obtained, I believe them still to be excessive, and that they must inevitably, frequently tax, not only the ocular, but the general health of students, especially those of weakly tendencies. I believe that a lengthening of the time required to secure a high school degree, by one year, would mitigate the severity of study all along the line, and enable scholars to emerge from their graduating exercises in better physical and mental condition, and would do the greatest good to the greatest number. I believe, besides this, that a more elastic curriculum is necessary to favor children having poor eyes, and poor health. The strictness of the grades should be modified, at least, and permission given for individual studies to be taken in quantities somewhat adaptable to the health of given individuals. Credit should be given for such studies, as they are finished, and the child allowed to graduate when all of the required studies have been completed. I am well aware, that this arrangement is not infrequently made in our public schools, but I think that such a course is not encouraged, and that children are made to feel a sense of mortification because they are falling below their grades or classes. I think many of the children should belong to *no* grade or class, but be allowed to acquire

their education, study by study, in a manner consistent with the proper development of the health. I do not mean to advocate the abandonment of grades and classes. This would be most unwise and undesirable, but I do feel that children with impaired ocular or general health should be cheerfully and creditably, not only allowed, but *advised* to take only such numbers of studies as will be consistent with a proper physical development. Such a course would lengthen the period of school life in many instances, but it would improve the average health of scholars, and this is of greater importance. Children should not be required to take so many studies that they have to work up two or three at home in the evening. If they study the major portion of the day, a growing and developing child should not be required to give up that mental and physical relaxation incident to an evening spent pleasantly at home amid sports, games, music light literature, etc. I do not mean to say that children should do no studying at home of an evening. A little study is not only harmless, but beneficial, but some children are compelled to work up three or four studies at home, and this is excessive. Work of this kind resulting in close confinement, bad atmosphere, and perhaps poor illumination and utter disregard of hygienic study methods, results in a lack of that refreshing sleep necessary to the proper nervous, mental and physical development of the child. However much care is manifested in the schools concerning the proper use of the eyes, it is difficult to regulate such work at home. Therefore the amount of required eye-service at home should be limited. The teacher never knows how the scholar learns his lesson at home. He may study lying down by a poor light, or face a brilliantly lighted lamp or gas jet for hours, or indulge in other habits injurious to proper ocular health. Children will also use their eyes in devouring light and sensational literature, impressed upon the poorest paper, with the poorest type and the poorest ink: and while we may wish to stop this evil, we must be aware of our inefficiency in accomplishing our desires. If this be true, and children's eyes will be abused in a manner that is thoroughly beyond our control, we must make some allowance for it and not impose too much ocular service at home, incident to the acquiring of an education. Ocular strain in schools can be much mitigated by frequent change of occupation, which may not be always a recess, but may be something in the nature of exercise of various kinds, such as calisthenics, gymnastics, marching, etc. Much improvement has been made along these lines of late years, but there is further room for improvement. Such changes have become quite a feature in many German schools, where ocular degeneration has become recognized and steps for improvement inaugurated. Statistics from some schools have shown that since frequent breaks of various kinds in the school session have been made, the ocular condition of students have manifestly improved. The semi-annual term examination for the determination of class standing is often detrimental to the eyes and health of students. It is a semi-annual period of intense, concentrated and continuous study, which often leaves in its wake impaired eyes and health. Can not some means be devised whereby these periods of over study and anxiety may be abated, and the standing of students secured in other ways, such as class records, quizzes, reviews, etc?

The architecture and location of school buildings is of great importance. Suitable and healthy loca-

tions should be obtained as far as possible. In cities, the nature of the soil is not always possible to be taken into consideration, nor is it so important, as city buildings are usually thoroughly well drained and plumbed. In the country, however, a well drained location should be chosen, without a clay sub-soil, and remote from malarial and other injurious environments. In cities, narrow streets with high buildings should be avoided, as they shut out the light and proper ventilation. School buildings should be away from factories, markets, etc., to avoid their distracting noises, exhalations, dust, etc. Ample grounds should be secured, upon all sides of the building, not only for maintaining proper air, light, etc., but in order that children may have plenty of room for games, etc., which are so conducive to the proper physical development of the child. Large, well lighted and dry cellars should be had for recreation on stormy days, and, where it is impossible to obtain a large tract of ground for the school building, it has been suggested that a flat roof be built with high surrounding walls and a roof garden be laid out in which children may play. The question of sufficient light in school buildings is of vital importance. To obtain this, other buildings should be at a distance equal to twice their height from the school building. The illumination of a school room should be of a quantity and quality that will amply light every portion of the room on a dark day. To secure this, the window surface should not be less than one-fifth or one-sixth of the floor, and the direction from which the illumination comes is a matter that is not particularly essential, although a north light is the steadiest and most constant; but many observers and teachers dislike it on account of the lack of sunlight, which they claim to be detrimental to the health and spirits. Scholars compelled to study by poor illumination will be found to carry the printed page close to the eye, in order to increase the quantity of retinal illumination, or to take advantage of the law that the illumination diminishes according to the square of the distance. This forces the accommodation and convergence of the optical axes, and causes undue congestion of the eyeball and surrounding tissues, which increases intraocular pressure and softens the coats of the eye, thus permitting an elongation of the optical axis, and the production of myopia. Windows should be at the side of the room, preferably the left side, and at the back. The lower portion of the window should be about three feet from the floor and extend to the ceiling, in order to obtain as much window space as possible. The margins of the window ledges should be beveled, both inside and out, to avoid shadows, and should not be placed on both sides of the room, as it would result in a confusing and injurious cross-light. There should be as little wall space on the sides where the windows are placed as possible, and the windows should be hinged at the top, in order to obtain proper ventilation without direct draughts. Blackboards should not be placed between windows, as it taxes the eye exceedingly to endeavor to decipher marks made upon a blackboard thus situated. The ceilings of a school room should be high, in order to secure good light and ventilation. Artificial illumination should be of a good quality and sufficient in quantity. A profusion of incandescent lights with glazed globes, grouped at frequent intervals, is the best illumination that can be secured, as it is white in character, intense in quality, and does not heat or vitiate the atmosphere. In order to carry

out the idea of a light school room, the walls should be painted in delicate shades of yellow, green, blue or light gray. The blackboards can be covered when not in use by light colored shades, of a similar color to that of the walls. The woodwork, desks, etc., should be all of light colored wood, in order to preserve as much illumination as possible. Window shades should be light colored, and should roll from both the top and bottom, with the possibility of their being long enough to roll up or down the full extent of the window surface.

The seats and desks is an item of great importance, and was first publicly mentioned by Henry Barnard in 1860. He pointed out the necessity of placing the seats close to the desks in order to avoid leaning forward. Seats and desks should be arranged in such a manner that the soles of the feet will rest securely upon the floor, and so that the erect posture is the most natural and the easiest for the scholar to assume. In order to obtain this the seats should be as wide as the thigh is long, measured from the inner bend of the knee to the back. It should be level and slightly concaved to prevent slipping forward. The front edge of the seat should be placed from one to two and a half inches underneath the inner edge of the desk. The top of the desk should be inclined toward the pupil at an angle of about 10 degrees, and must be low enough to allow the forearm of the pupil to rest lightly upon it without raising the shoulder when in the act of writing, but sufficiently high to avoid the necessity for stooping in order to reach it. The lower part of the back and pelvis should be supported by a rest easily felt while sitting upright. It seems almost unnecessary to state that desks should be of different sizes to suit the pupils, and yet I have frequently looked into schoolrooms where but little attention was paid to this point. Some of the manufacturers construct desks in such a manner that by the adjustment of screws, etc., every desk in the room can be made of a proper size to any child who will be likely to be in that particular schoolroom. By using desks of this kind, the fitting of scholars to their desks will be an important procedure at the commencement of each school year. Of course, proper desks or seats will not solve the problem, some children have weak backs or are otherwise bodily affected and seem truly unable to sit in a schoolroom without half reclining upon a desk, and it is questionable whether children of this kind should be required to attend school sessions steadily. Other children are lazy and slouchy in their habits, and this will call for frequent admonishment on the part of their teacher.

Blackboards should be kept clean and have unglazed surfaces, and the figures, lines, etc., that are marked upon them should be of a size and character that can be easily seen without straining the eyes of the pupils. Some authorities have recommended the use of white boards with black chalk instead of blackboards with white chalk, as black figures on a white surface can unquestionably be seen easier and farther than white figures on a black surface. I think a majority of practical educators, however, believe that the white boards with black chalk are extremely objectionable, on account of the constant and distasteful soiling of the hands. If the blackboards are kept clean, the white crayon marks will be found to be sufficiently legible for all practical purposes.

Slates are justly becoming unpopular in schools, whether they be black or white, on account of the

foul and unhealthy condition in which they become. If slates are used, however, the white slates are to be preferred, as the black marks upon the white surface are much less trying to the eye than the faint gray marks of the pencil upon the old-fashioned slates. The best material with which to perform this kind of work is whited unglazed paper and black ink, with a stub pen capable of making heavy strokes. Maps and charts are important articles of school furniture and easy to teach with, if the marks upon them are large and legible. The groundwork upon which such maps are printed should be of a white or yellow color, as characters printed upon dark shades, such as red or blue are not so easily distinguished. The study of geography as taught by hand atlases, with varied colors, lines, figures, printing, etc., is very trying, and is probably more injurious to the eye than any other study. Great care should, therefore, be taken in the printing of geographic text-books and maps, and such books should be chosen by school authorities as will be least injurious to the visual organs of the child.

The manufacture of text-books for schools is a subject of great importance. Books should be of a size that can be easily handled, and the paper used in the construction should be of good quality, non-translucent, reasonably thick and of white or cream color. The printing should be first-class in every particular. The letters should be black, clear and of sufficient size for easy reading. The lines should have good distances between them. Long lines should be avoided, as extra accommodation is required to follow them, and if a page must be wide it is better to divide its contents into columns.

A great deal of discussion has lately arisen as to whether the slanting handwriting heretofore taught in our schools should be continued, or whether scholars should be instructed as to the methods of acquiring an erect handwriting. Fahrner, in 1897, said, "we allow our children to grow crooked in order that their handwriting may be nicely slanted." There can be no question but that vertical handwriting is less injurious to the eye than the slanted variety. In writing after the vertical method, the paper is directly in front of the scholar, and therefore the page is seen equally well with both eyes, which will accordingly work together. Besides this, the strokes are stronger and less hair lines will be seen than in the slanted variety. Besides, the vertical method of writing favors upright sitting, which is in itself a sufficient reason for its adoption.

The tendency to lean over while sitting at the desk is very strong with some scholars, even though the school authorities have provided them with proper desks and seats. To obviate this tendency, many forms of head rests or face rests have been suggested, and of them all Kallman's face rest is probably the best. These rests are fastened to the desk and assume a vertical position with a loop at the extremity through which the face emerges. When these rests are fastened into the desks it becomes impossible for the child to lean over when reading, and many German schools have adopted Kallman's face rests with the utmost satisfaction.

The method which I proposed in February, 1895, for the detection of most ocular diseases in children, together with measures for their relief, is doubtless familiar to all. I have from time to time modified the original plan until I believe it to be now as nearly as perfect as such a plan can be in our American public schools.

The statistical papers and warning cards now in use in the Minneapolis schools are now used quite generally throughout the United States, and are giving satisfaction wherever tried. The results have been distinctly beneficial to the coming generation, and in Minneapolis the plan is in great favor with teachers, scholars, parents and the public at large, and has been productive of benefit to thousands of cases, especially since people are learning that the tests are for the development of most all ocular diseases and not merely for the fitting of glasses, and since they have also learned that an eye doctor and not an optician is the proper person to consult if a warning card is deemed a necessity.

Those aural diseases which will be most frequently observed by teachers are running or mattering ears and deafness. The former are usually produced from blood diseases, inherited or acquired, from catching cold or from catarrhal affections of the throat and nose. They can usually be detected by the teacher if the child complains of earache if care is taken to look into each ear, as far as possible, by a good light for the detection of matter or pus, or if either ear emits a foul odor. If any of these conditions obtain, the child should be advised to consult an aurist.

I would recommend that the following questions be added to the statistical blanks now in use in the Minneapolis schools:

1. Does the pupil frequently complain of earache in either ear?

2. Does matter (or pus) flow from either ear?

3. Does a foul odor proceed from either ear?

If an affirmative answer obtains from any of these questions the child should be sent to an ear doctor, as often questions not of diseased ears but life and death itself are at issue. The examination for odor will be most distasteful to some teachers, and under such circumstances it may be omitted.

A deaf child is an apparently stupid child and is deprived to a greater or less extent of an important sense which was intended as one of the means of obtaining a knowledge of the world. He is therefore unequally equipped for the battle of life and obtains an education disadvantageously, and is frequently called stupid, listless and unambitious, when in reality he is merely deaf. The time to relieve such conditions is in early life while physical tissues are pliable, and not in later years when relief is improbable and cure well nigh impossible.

Deafness may be due to the presence of a mattering (or purulent) ear with its destructive tissue changes, which causes will be developed under the set of questions just enumerated, or it may be due to catarrhal conditions or changes of the throat, nose or Eustachian tube. One of the most frequent causes of deafness in children is what is known as adenoid vegetations in the vault of the pharynx, or enlarged bunches of tissue growing from the upper portion of the throat and interfering with the proper inhalation and exhalation of air through the nostrils, and the proper aeration of the middle ear through the Eustachian tubes. The same unfortunate conditions exist frequently in children possessing abnormally large tonsils. Children of this kind are apt to become deaf and develop into what are known as "mouth breathers," because they habitually breathe through their mouth instead of their nostrils, giving them a peculiarly stupid and vacant appearance. The improper aeration of the air passages predisposes to lung

diseases, and the perpetual expansion of the mouth and the lack of nasal breathing produce a lateral contraction of the nose and vault of the mouth which, together with the contracted upper lip, gives to the countenance a characteristic appearance, which once seen is not easily forgotten. Almost inevitably a child with such a physiognomy is more or less deaf and has throat or nose obstructions, or both. Other catarrhal conditions may cause deafness and frequently do, but such events occur more frequently in adults. The deafness of children is usually dependent upon organized nose or throat obstructions. These conditions can be easily detected by an unprofessional observer by the appearance of the child and the asking of a few simple questions.

Before suggesting these questions let me say that while there are many tests for hearing, only two seem feasible for use in school examination, viz., the spoken voice and the tick of a good sized watch. To use the former the child's back should be turned to the teacher, and an assistant should plug up first one ear and then the other with a cloth over the finger. The teacher should then step away about twenty feet, and ask the child in a low but distinct voice, a direct question, requiring a direct answer. If, after one or two tests the child fails to hear the spoken words in either ear, he should be sent to an ear doctor. He should be further tested in the same way in both ears, by the tick of a good sized watch, which should be placed six or eight feet away, and gradually moved toward the child, on the side upon which he is being tested. The watch should be heard at least three feet away, and if it is not heard by both ears at that distance, the child should be sent to an ear doctor.

Having now shown you how hearing may be simply tested, let me suggest some pertinent questions, to be added to the statistical blanks previously recommended, which will develop the existence of the abnormal conditions, which I have endeavored to briefly describe:

1. Does the pupil fail to hear a low and distinct voice, at twenty feet, with each ear?
2. Does the pupil fail to hear the tick of a good sized watch at three feet, with each ear?
3. Can matter be seen flowing from either ear, or does a foul odor proceed from either ear?
4. Does the child fail to breathe freely from either nostril, when the other nostril is closed with the finger?
5. Is the child an habitual "mouth breather"?

If an affirmative answer is given to any of these questions the child should be sent to an ear doctor.

The results of intelligent treatment upon such diseases in children are exceedingly satisfactory, and if the young sufferers can be placed under proper care sufficiently early, an immense amount of good may be accomplished to the coming generation.

92 State Street.

THE BEST METHODS OF SURGICAL STERILIZATION.

Presented in the Fourth Annual Meeting of the American Academy of Railway Surgeons at Chicago, Ill., Oct. 6-8, 1897.

BY EDUARD BOECKMANN, M.D.

CONSULTING SURGEON CHICAGO GREAT WESTERN RAILWAY.
ST. PAUL, MINN.

It is indeed very fortunate that the surgical bacteria are, comparatively speaking, so little resistant that surgical sterilization can be reduced to such a degree

of simplicity that it may be carried out on short notice, not only in hospitals, but also under the open sky, not only in private practice, but also in offices, by reasonable means and in reasonable time. While surgical sterilization is open to improvement and does steadily improve, it is a source of some regret that the best methods of accomplishing surgical sterilization are still somewhat in dispute.

If I am justified in considering the various manuals on this topic, as standards for the teachings and practice of surgical sterilization in the respective countries, we have three principal schools before us: 1, the English school, which practically teaches the destruction of pyogenic, consequently non-spore-bearing bacteria only. (W. Watson Cheyne: "The Treatment of Wounds, Ulcers and Abscesses," Philadelphia, 1895); 2, the German school, which advocates the extermination of all surgical bacteria, spore-bearing or not, pyogenic or not. (C. Schimmelbusch: "Anleitung zur aseptischen Wundbehandlung," Berlin, 1893); 3, the French school, which in reality aims at the destruction of all kinds of bacteria, pathogenic or not, consequently not only at surgical but also at bacteriologic sterility. (Felix Terrier and M. Peraire: "Petit Manuel d'Antisepsie et d'Asepsie chirurgicales," Paris, 1893.)

The practical result of these three different views is, that the Englishman is perfectly content with chemical sterilization, while the German considers thermic sterilization the best method, as does the Frenchman.

If the Englishman is right he has the advantage of the simplest method of sterilization, as almost everything is prepared with the aid of a cold solution of carbolic acid; if the German is right, and he has at least the sympathy of the majority of surgeons, sterilizers for boiling water and for ordinary steam, which the Englishman has no use for, are indispensable; and if the Frenchman is right, surgical sterilization will never become popular outside of hospitals, as his sterilizers are both expensive and cumbersome, as they are constructed for high pressure.

Surgical sterilization means, naturally, destruction of surgical bacteria, and is a part only of asepsis, which means absence of all septic material, consequently not only of bacteria, but also of impurities of a chemotactic nature. In our surgical work we aim consequently, not only at sterility but at cleanliness (atotoxicity) as well. This fact is admitted by all schools, and mechanical sterilization is therefore recognized as a preliminary measure of the highest importance. Chemic and thermic sterilization can not satisfactorily cleanse all our various articles: on the other hand, mechanical sterilization is not able to sterilize them perfectly, although this last method removes the majority of the bacteria at the same time that it makes the articles atoxic.

While it is of some importance to remove chemic impurities of all kinds, and all schools, therefore, indulge in washing, scrubbing, scraping and shaving, and while mechanical sterilization at the same time means at least three-fourths sterility, we must insist upon complete destruction of our real enemies. The question now is, is it enough to destroy the less resistant pyogenic bacteria (English), or is it necessary to remove and kill all known surgical bacteria and their spores (German), or finally, should we endeavor to obtain a real bacteriologic sterility (French)?

It must be admitted that failures in our surgical work, because of imperfect sterilization, are invariably

due to sepsis, *i. e.*, to the action of pyogenic, not spore-bearing bacteria.

Only once or twice have we heard that the patient died from anthrax or tetanus. When did we hear that our patient succumbed to tubercular infection because of faulty sterilization? Of *vibrio septique* (malignant edema) the same may be said. It is always sepsis, and so far the Englishman is, in my opinion, practically right when he claims that surgical sterilization of these bacteria is enough. Could we only rest assured that chemic sterilization would accomplish this in a practical manner, there would be no need of thermic sterilizers requiring proper apparatus and heating plants.

But fascinating as chemic sterilization is, severe criticism may be entered against it. The stronghold of chemic sterilization is by no means surgical sterilization but antiseptic surgery, which forgives a good many minor surgical sins and shows clemency to gross mistakes. Antiseptic surgery cripples bacteria for some time without destroying them completely, thus giving nature time to organize the defense and prepare for the offensive. But it must be remembered that chemicals are disposed of in the organism sooner than bacteria, and as long as we do not possess a non-irritating chemical which will stick to the tissues until the process of repair is finished, antiseptic surgery can not replace surgical sterilization. When the Englishman claims to obtain just as good, indeed better results, with chemic sterilization than those who prefer thermic, and if there is any truth in such a proposition it must be due to antiseptic surgery and not to chemic sterilization. There is no objection to judicious antiseptic surgery as every operation of some length includes infection of some degree, and if everything has been properly sterilized mild antiseptics only is required, and the milder the antiseptic procedures are the better, as all chemicals are necessarily more or less cell-poisons, the more so the more concentrated they are. Good surgery can undoubtedly be done by poor surgeons with the aid of chemicals; good surgeons have use for them only to a limited extent.

Seen, therefore, in the light of antiseptics, chemicals are of great value; seen in the light of germicides, they have a very limited field in surgical sterilization. Nobody denies that certain chemicals are germicides in a proper concentration, but they have no immediate action. Watson Cheyne makes this statement: "we may take it as an axiom that any substance which is thoroughly soaked in a 1 to 20 carbolic acid watery solution for twenty-four, or say forty-eight hours is absolutely disinfected." This, if true, means nothing more nor less than that chemic sterilization is impracticable.

The bacteriologist has not as yet been able to settle the question of the germicidal action of any given solution on pure cultures of surgical bacteria and probably never will, as it is almost impossible to eliminate the chemical before the test thread, or whatever is employed, is transferred to the culture medium. The action of chemicals must be studied in the operating room, but if a certain chemical appears to work satisfactorily there, like carbolic acid in the English hospitals (Cheyne), the only conclusion we may draw is, that antiseptic surgery is justifiable, but not that chemicals are germicides.

Chemic sterilization is very slow under the best circumstances, injurious to our surgical materials, unpleasant to the surgeon and even dangerous to our

patients. "The chemic method of disinfection is therefore a make-shift and is only to be employed for certain materials and in certain conditions" (Kocher). Every sensible surgeon will indorse the statement of the eminent Swiss surgeon, and employ heat in some form or other whenever it is possible, as thermic sterilization is our best means of disinfection, having the important advantage over chemic sterilization, that it is mathematical, leaving no difference of opinion between the surgeon and the bacteriologist, and no doubt as to its reliability.

Thermic sterilization may be more complicated and expensive than chemic, as proper apparatus and fire are necessary, but what little we spend in money we gain in time, as this kind of sterilization acts in as many minutes as the chemic does in days; and to know that we, in a given case, have fully complied with the strictest laws governing thorough sterilization is a great satisfaction. Those who prefer antiseptics to asepsis can not possibly have any objection to asepsis itself, as they can supplement it with antiseptics at their pleasure and very easily, and it is a wonder to me that the English school will not see the great advantage in such a combined method.

Boiling water is the first, last and best sterilizing agent in surgery. Steam ranges next to boiling water, while hot air is only effective when its temperature is raised to the neighborhood of 300 degrees F. and continued for hours. The only trouble of any importance with thermic sterilization is, that it can not be employed for all purposes; but wherever it is applicable heat should be used, and I believe it to be little short of carelessness to neglect this method when the circumstances otherwise permit of its employment. Sterilization, pure and simple, as it is effected by heat only, does not make good surgeons and is dangerous in the hands of poor ones, who can do better with antiseptic surgery. The mixed method, mechanical and thermic sterilization combined with judicious antiseptics, is recommendable to all surgeons, good as well as poor.

Having considered the different methods of surgical sterilization in general as to their real superiority, let us now take up some of the most prominent details with reference to the best methods to be pursued.

SKIN STERILIZATION.

English method.—This includes shaving, scraping, thorough washing with soap and a mixture of 1 to 20 carbolic acid lotion containing 1 part in 500 of corrosive sublimate in solution, saturation of the surface with turpentine and then again thorough washing with soap and the above mixture, employing a nail-brush; a five minutes performance.

German method.—This requires shaving, scraping, washing and brushing with soap and warmest possible water, then drying with sterile gauze, saturation with 80 per cent. alcohol and brushing with 1 to 2000 sublimate solution.

French method.—This is accomplished by shaving, scraping, washing and brushing with soap and sterile (filtered) water, saturation with ether and then brushing in a 1 to 2000 sublimate solution.

There is evidently not much difference in these three methods, and they appear to be equally elaborate in spite of Watson Cheyne's insinuation that "abroad disinfection of the skin is a very elaborate process." It is admitted that thermic sterilization can not apply to the skin; it is likewise admitted that the best

methods of disinfection of the skin are the mechanical removal of the impurities, but when Cheyne in admitting this writes, "and this can only be done by the application to it of suitable antiseptic substances," it is difficult to know what he means.

In cleansing the skin mechanically it is but common sense to use the warmest possible water. It is likewise but common sense to use sterile (and running water if procurable). As to turpentine, alcohol or ether, I believe it is the intention of the different schools that they shall add to the mechanical disinfection by their ability to dissolve impurities of various kinds, and they certainly do this, turpentine first, then ether and alcohol last, but it is supposed that they will exhibit an antiseptic property as well. In this respect also turpentine ranges above the others, alcohol coming last.

Whatever may be the case experience has shown that turpentine, ether and alcohol are very valuable agents in the disinfection of the skin, and I do not think it makes much difference which one is preferred. The *modus operandi* is, however, not very clear. As ether and alcohol act very unpleasantly on my own skin, I have of late taken up the English idea with turpentine, but the few seconds the skin can stand saturation with turpentine is so short that I can not possibly attribute any antiseptic influence to it. It cleanses the skin beautifully and leaves a coating of resin, to which I attach much importance, and mainly attribute its beneficial influence. For years I have been in the habit of impregnating the skin with sterilized lanolin as the finishing touch, in order to return to it in a sterile form what I have deprived it of in an infected one, and at the same time cover up the deeper-seated bacteria. Turpentine dissolves the fat, but in return it varnishes the skin and covers up the bacteria more perfectly than lanolin, and we can understand how water does not take effect on the skin treated with turpentine. I am inclined to believe that this varnishing constitutes the antiseptic properties of turpentine, and that something similar takes place when using ether or alcohol. Turpentine is cheap, convenient and always at hand in proper condition without any special preparation.

As for antiseptics in disinfection of the skin I leave them more and more behind. I prefer lysol to sublimate, carbolic acid and the rest, but I use it before the impregnation with turpentine, as it takes no effect when the skin is varnished. If antiseptics like carbolic acid are forced into the skin they will undoubtedly cripple the deeper bacteria, but if they are liberated during the operation and transferred to the wound, the antiseptic is, as above stated, soon disposed of and the bacteria may revive and thrive in the more or less injured tissues.

The skin can not naturally be properly sterilized through its entire thickness. The surface may be pretty well prepared by mechanical means, so that scrapings will not develop any cultures, but it is vain to try to sterilize the adnexa, and bacteria inhabiting these parts, however few and little virulent they may be, may be liberated during the operation either by perspiration or manipulation, not to mention that the skin of the operation-field exposes bacteria the moment the incision is made. For this last reason it is certainly proper to prepare the operation-field a day or two beforehand, and cover it with an antiseptic dressing in the hope that this prolonged saturation may actually destroy the vitality of the deeper bacterin.

The knife ought to be cleansed anew after the skin has been cut through. Covering up of the skin bacteria is not a new idea. Recently it has been revived and thin, delicate rubber gloves have been recommended. I prefer the turpentine process, as I need all the sensitiveness in my fingers nature has given them.

The best method of surgical sterilization of the skin is this: after shaving the operation-field (not the operators' hands), brush the skin with a stiff, preferably sterile brush, in hottest possible, preferably sterile and running water for several minutes; cleanse the nails and repeat the scrubbing (the surgeon who believes in impregnating the skin with one of the ordinary antiseptics, lysol, sublimate, carbolic acid, permanganate of potash, etc., should use it before varnishing with turpentine); dry the skin with sterile gauze, impregnate it with turpentine and remove the oil with sterile warm water or a mild antiseptic solution (antiseptic surgery). The whole procedure ought to consume about ten minutes.

STERILIZATION OF INSTRUMENTS.

English school requires immersion for two or three hours before operation in a 1 to 20 carbolic acid solution.

German school requires boiling for five minutes in 1 per cent. solution of carbonate of sodium.

French school includes prolonged boiling in $\frac{1}{2}$ per cent. carbonate of potassium solution, dry heat, and a variety of other methods.

It is fortunate, according to Watson Cheyne, that a comparatively short immersion in a 1 to 20 carbolic acid solution will remedy any accidental contamination, which may occur after the instruments are taken out of the glass press, where they are kept and where they are in reality pure. And if an instrument during the operation drops to the floor, it is effectually and rapidly rendered aseptic by dipping it for a few seconds in undiluted carbolic acid.

About the two or three hours immersion, Watson Cheyne says that the disinfection is "generally quite satisfactorily accomplished." When a "comparatively short immersion remedies any accidental contamination," why does not the English surgeon stick to the short immersion, which according to the above statement is more reliable than the long one?

At the same time that Cheyne evidently sterilizes his instruments by the aid of carbolic acid, he makes the strange statement that he does not, as a rule, boil his instruments, as he sees no advantage in it. Still he confesses that it is certainly very convenient to have a vessel of water boiling during the operation, in case any instrument, which has not been previously prepared, is required, or in case an instrument falls on the floor, on a blanket, etc.; such an instrument can be immersed in the boiling water for a few minutes, and then be relied on as being thoroughly aseptic. I am at a loss to see the superiority of the English method of sterilizing instruments according to Cheyne's own statement.

The German method of boiling the instruments for a few minutes in soda solution, is so simple, so convenient, so quick, so little injurious to the instruments and so absolutely reliable, that this method must be considered the ideal one. For that surgeon who keeps his instruments in good order—what we all should do—it is sufficient to pour boiling water on them and let the water cool off. That the addition to

the boiling water of an alkali raises the temperature and prevents rusting is known to all, and it is immaterial if carbonate of sodium, carbonate of potassium or soap is used. Lately I prefer liquor potassæ to other agents, as it gives no precipitate and is always at hand, as we use it in our urinalysis. The instruments come out of boiling solution of potassium bright, clean, sharp and aseptic—undoubtedly the best method of sterilization of the instruments.

It is a source of some regret that we do not command a practical method of keeping our instruments at hand all the time sterile. Many suggestions have been offered, but they have failed to prove acceptable. When, however, we consider that in all cases we will have to prepare our own hands and the patient's field of operation the regret is not of lamentable proportions. The time it requires to prepare the skin is all the time required to sterilize our instruments by the boiling process.

The Frenchmen are extravagant in their sterilization of the instruments, due to the fact that they aim at bacteriologic, while they speak of surgical sterilization. Boiling for half an hour is hardly considered enough; the addition of $\frac{1}{2}$ per cent. carbonate of potassium is looked upon as better; some use hot air, others boiling oil, vaselin, glycerin, etc. Such methods are superfluous and to be rejected when we have simpler ones that have stood scientific and practical tests.

Many find that boiling water is detrimental to instruments, as they become rusty and dull. This is true, if certain precautions are not taken. The water should preferably be rain or distilled water, an alkali should be added, and the instruments not immersed before the water is boiling, and the boiling should not last more than from two to five minutes. To wrap the cutting instruments up in cotton is an additional safeguard. Under these circumstances the instruments will not suffer unnecessarily. But mistakes are continually being made and people are hunting for a safe, quick, chemie method and formalin has come conspicuously to the front, particularly among the oculists. Time will show that formalin has no advantage over carbolic acid or other chemicals. Formalin is a very much over-rated agent and the formalin craze, which has lasted about a couple of years, is fortunately gradually subsiding. Formalin sticks a long time to the various articles exposed to its action, and this circumstance is responsible for the exalted ideas of its sterilizing superiority. Whenever thermic sterilization can be used it is imperative to choose this method on account of its mathematical accuracy. If not practicable, chemicals may be substituted for it as they are better than nothing.

DRESSINGS.

English school.—Gauze is impregnated with antiseptics.

German school.—Gauze is sterilized by ordinary steam (low).

French school.—Gauze is sterilized in autoclave (high steam).

The Englishman sterilizes his dressings by the aid of carbolic acid, corrosive sublimate or both. There is no doubt that dressings may be sterilized by chemicals if they remain long enough in a solution of proper strength. It is safe to say, it requires several days—Cheyne thinks two—for a 5 per cent. solution of carbolic acid to accomplish sterilization; and the

same holds good with a 1-1000 sublimate solution. In so far, there is no difficulty in having properly sterilized dressings at hand, when needed. But dressings will suffer by a prolonged stay in the antiseptic solution, and they can produce harmful results locally as well as generally, for which reason they must be wrung out in a weaker solution or sterile water, before being applied. Moreover, as dry dressings are preferable to moist, for well known reasons, it is common for manufacturers to dry the chemically sterilized dressings and put them up in containers. These factory-made dressings, for which there is an enormous sale throughout the world, is a great humbug in spite of the undoubtedly well-meant efforts of the manufacturing houses to make them reliable.

First, it has been proven over and over again that factory-made antiseptic dressings are more or less full of bacteria, as they have been handled by ignorant and irresponsible hands after having been removed from the solution: second, chemicals do not sterilize unless they are in an active form, that means, in solution. This holds pre-eminently good with sublimate gauze, and in all probability, also, with carbolic acid dressings. The oozing from the wound will precipitate the chemicals and make them inert. As for Credé's silver gauze, it remains to be shown if the oozing dissolves the silver and makes it active. Dressings sterilized by chemicals are only reliable when they are conveyed directly from the fluid to the wound.

The factories claim that their antiseptic dressings have been sterilized over again, once or twice, in their containers by steam. As steam must penetrate, condense its moisture, revaporize this, and at the same time expel all air, everybody will understand the great humbug of sterilizing antiseptic goods in containers, which are either impregnable by steam or do not allow the escape of air.

The German sterilizes his dressings by steam at the temperature of boiling water (212 degrees F., low steam). He places the dressings, which have been thoroughly cleansed by washing and dried beforehand, in a steam sterilizer, which is so constructed that the steam enters the sterilizing chamber from above and escapes below, thus expelling all air and at the same time sterilizing every particle of the articles contained. The whole process takes about half an hour and the sterilized dressings are taken directly from the sterilizer and conveyed to the wound without being manipulated by suspicious hands.

Several devices have been recommended to keep such sterilized dressings ready for use all the time. The most simple and practical is that of Bloch: The gauze is wrapped up in a double layer of filtering paper, tied, marked and put in the sterilizer. The steam will penetrate the filtering paper with the same ease with which it penetrates the dressings, thus sterilizing it at the same time. (Steam can not penetrate ordinary paper.) After complete sterilization and drying, the contents of these packages will remain sterile so long as the filtering paper remains dry. Any one can unroll the outer layer, and the surgeon picks out the inner, which contains the gauze. It is strange that the zealous and willing manufacturer of surgical dressings has not taken up this idea, which dispenses with the objection above, that the sterilization process should be the last and not the first one. The market is full of plain sterilized gauze. I will heartily recommend the profession to buy their gauze from these houses, as the gauze has been thoroughly

cleaned, dried and sterilized. But do not have too much confidence in the sterilization, but repeat the process in your own sterilizer. The German way of sterilizing dressings has proved to be perfectly reliable, and sterilizers constructed for this process are simple, inexpensive, durable and portable, qualities which enable every surgeon to accomplish his own sterilizing under any and all circumstances. For complete particulars in regard to steam sterilization and steam sterilizers I refer to my earlier writings, to which I have nothing to add.

Steam sterilization of dressings is unquestionably the best method, as in a short time and with very little expense and trouble it makes the dressings perfectly aseptic, and when they are first rendered aseptic it is an easy thing to make them antiseptic, if so desired, by plunging them into an antiseptic, sterile solution, or by dusting them or the wound with an antiseptic powder.

The Frenchman thinks his method of sterilizing dressings is superior to that of the German, because he can expose them to a much higher temperature in his autoclaves (high steam). There is no objection to bacteriologic sterilization of dressings which the Frenchman can obtain, but surgical sterilization, of which we speak, is effected by the German method to perfection: besides the autoclaves are expensive and cumbersome; they are stationary apparatus and do not give the dry dressings that can be obtained in sterilizers constructed on the German principle. Their only advantage, to my mind, is the fine show they make in a hospital and that they may be connected with the pre-existing steam plant, so that no extra fire is required.

SUTURES AND LIGATURES.

English school.—Silk is kept for a few days in 1 to 20 carbolic acid solution. Catgut is soaked in the same solution for at least a week.

German school.—Silk is sterilized by steam or by boiling; catgut by chemicals.

French school.—Silk is sterilized by boiling, first in filtered water, then in antiseptic solutions, and finally steamed in the autoclave. Catgut is sterilized by dry heat.

I have only mentioned silk and catgut as representatives of inabsorbable and absorbable suturing and ligating materials. Silk: As this material can remain in strong antiseptic solutions without detriment almost any length of time it is evident that thorough sterilization can be accomplished in this manner, and consequently there is no objection to chemical sterilization according to the English school of this particular material. But the advantage of having sterile silk present at all times is of doubtful utility. The needle, the needle-holder, etc., can not well be kept in a sterile form, and the surgeon who sterilizes his instruments by boiling will naturally prefer to boil his silk at the same time. It is no advantage in silk sterilized by chemicals that it is antiseptic. The chemical contained in the silk is certainly of minor importance as to poisonous action, locally or generally, because of the small quantity contained; for inabsorbable material it is enough that it is sterile. The best method of sterilizing silk is to boil it with the instruments, but in a separate container. The Frenchman is just as extravagant in his treatment of silk as he is in his sterilization of all other articles.

Catgut: With reference to this ideal suturing and

ligating material, there is no longer any doubt that it can be reliably sterilized, and with comparative ease. But Schimmelbusch, in this one instance, turns his back on thermic sterilization, which he considers very difficult, complicated, and requiring minute surveillance, which prevents its general employment. I commend the Frenchman who advocates dry heat (the method of Larochette).

Catgut can not be boiled or steamed; if thermic sterilization is to be used, it must be in the form of dry heat (Reverdin-Benckisser). If we possess a proper hot air sterilizer in which the temperature can be gradually raised to about 280 degrees F., and maintained for hours, we have a simple and perfectly reliable method of sterilizing catgut. It has been said that catgut sterilized by dry heat is not always perfectly sterile, but if the laws governing dry heat sterilization have been properly complied with, in a sterilizer correctly constructed, surgical sterilization is attained.

There is no doubt that catgut can be sterilized by a variety of chemicals, but as it is, first, antiseptic as well, it is difficult to say what shall be ascribed to the antiseptic, and what to the supposed sterility; and second, it requires days and weeks for the antiseptic, and only hours for the heat to accomplish its purpose.

Aseptic catgut sterilized by dry heat is a good culture medium for bacteria, and it takes a clean surgeon to handle it successfully. Therefore, it is the problem of the future to impregnate catgut with a non-irritating antiseptic which will remain with it until the last fiber is absorbed; when this is attained, then, and only then can we speak of ideal catgut.

DISCUSSION.

Dr. JOHN E. OWENS of Chicago—A few years ago I was purchasing my catgut from a certain place. Two patients were sent to me by a physician from the same town. I operated upon one patient, making an amputation of the breast. Intense septicemia rapidly set in and the patient died. She was considered a strong healthy woman otherwise. The same day I operated on the other patient, the operation consisting in opening the abdominal cavity to clear up the diagnosis. I found malignant disease of the liver at the hilum, which was in such relation to the vessels that an operation was deemed impracticable. I simply made a short incision, introduced the fingers and was able to get all the information desired. The patient was a debilitated, nervous man, and in three days he was dead. I was horrified at the death of these two patients. I went home and burned all my clothes, I did not know really what to do. I thought of some defect in the preparation of the instruments. The operations were performed in a hospital in which I never before operated. Then I studied and tried to work out the problem. I had some urine examined and found it was loaded with anthrax bacilli, and then I had the catgut which I had used in both cases examined, cultures made from it and anthrax bacilli were found. This leads me to say that the use of commercial catgut ought never to be thought of unless we know exactly how it is prepared. We immediately procured the apparatus of Dr. Boeckmann for use at St. Luke's Hospital, and we have since been using catgut prepared after his method. I have also been using it in private practice as prepared by him. We do not use catgut until we finally secure the degree of heat. But we had considerable difficulty in obtaining this heat owing largely to the gas stove that was used. The plate at the bottom of the catgut sterilizer was too small, and enough heat could not be utilized for the purpose, and instead of one row of jets we substituted another one, or two or three, and in that way we had no difficulty in getting a temperature of 200 degrees, but I have never touched commercial catgut since.

Dr. ARTHUR D. BEVAN of Chicago—I believe catgut can be sterilized thoroughly by a number of different methods. This, however, does not carry with it primary wound-healing if catgut is used, because undoubtedly it does contain at times, if not always, certain irritating and toxic substances which will so irritate the tissues as to produce suppuration and because a pathogenic germ is the essential factor, and it will produce

conditions which in a given case are sufficiently weighty to produce suppuration, because no surgical operation is absolutely aseptic. We must regard all surgical wounds as those in which bacteria are present that are capable of producing suppuration. I mean all wounds in which the skin is involved, or in which any of the hollow viscera are implicated. If we accept this no wound is absolutely aseptic, and following out this line of reasoning we must conclude that many wounds heal in an aseptic way, what we call normal wound-healing without any reaction and without any appearance of pus. In those cases we must suppose that the few germs present are not sufficient to infect the wound and the tissues are well taken care of. If in a case we add to the tissues an irritating substance, it requires a certain effort on the part of the tissues to remove it, and we very frequently add sufficient factors to bring about a suppuration which otherwise would not occur. I have watched this very carefully in some of my cases, and I am positive that we have many cases of infection from catgut in which the catgut is sterile. I have demonstrated this by making repeated cultures in catgut prepared in a number of ways, by boiling in alcohol, by the old method of ether and alcohol and bichlorid, by the catgut prepared by dry heat, and the catgut prepared by boiling after it had been hardened in formalin. If we accept the statements which I have made, or if this can be demonstrated it brings up the subject of the best method of surgical sterilization in a very much broader way, so that we must discuss all of the factors which prevent primary wound-healing, if we accept the fact that no wound is sterile, that the factors which produce suppuration are many times clinical, not necessarily the germs themselves, because we always have them present, but other added factors. I have followed out this line of reasoning in a systematic manner during the last year or two, and I believe the study of other factors besides the elimination of the germs is very important. Those factors are very many and will be noticed in our clinical work as, for instance, tension. You will approximate the wound with tension; your wound and your dressings are sterile; you have tension present; tension produces necrosis; you invariably have some germs deep in the skin and the tension is the cause of failure of primary union. In the same way we may consider pressure. I have had several cases in which the wound was absolutely sterile, yet pressure applied by a very hard dressing over the stump of an amputated leg will produce necrosis. We always have germs present later and infect the wound. In the same way we find that the presence of dead and mutilated tissue is an important factor. A wound in which we have clean incisions, no tearing, will unite much more readily than one in which we have tearing and gross tissue. The elimination of blood clots is an important factor.

Another point is the general condition of the individual himself. The subject is well illustrated by a case which has been in my hands recently. I operated for hernia in a diabetic patient. There had been at no time marked suppuration. The wound healed primarily, following which there was a little fluctuation two weeks after over the line of wound healing. I found apparently sterile fluid containing some leucocytes and later slight suppuration. Undoubtedly the general condition of the patient had much to do with this.

Another point is infection from the intestinal tract. Intestinal toxemia undoubtedly does occur quite frequently. How else can we explain such a case as this, for instance, primary healing of the wound of a shoulder joint amputation, the entire wound apparently sterile, and yet within ten days there was slight boggy over the wound, it is opened and some suppuration is observed? The details in this case were failure on part of the nurse and interne to carry them out. The patient being rather ignorant was allowed to go a week without evacuation of the bowels. In examining the pus the bacillus coli communis was found. This case seemed to be a clear one of infection of the wound from absorption of the intestinal contents. I must apologize for introducing this feature of surgical work, but still it impresses me as being very important, because many surgeons place the entire responsibility of surgical operations in primary wound healing upon the aseptic treatment. There are many other factors that are as important almost as the reduction of infection to a minimum, which is certainly all we can ever accomplish in the field of operation.

Dr. R. HARVEY REED of Columbus, Ohio—In the infection of wounds I have noticed that the infection only extends to the integument and down to the deep fascia. For instance, in the use of silk-worm gut, used for the purpose of suturing the abdominal wall, the interrupted sutures going from the integument through into the abdominal cavity, and then out again on the other side, and yet I have noticed when the silk-worm gut was sterilized completely we would have, after a few days or a week perhaps, a stitch abscess. I have observed in those

cases that the muscles and peritoneum were completely united, there being no trouble whatever, notwithstanding the suture had gone through all of these layers. If you take out the suture you will simply find infection extending down to the deep fascia and no farther. Now, it occurs to me that this does not come from pressure nor from infection due to the suture material which was used, whether it be silk, silk-worm gut, catgut, or whatever it may be. If the infection was due to the suture it should have extended to the peritoneum, and especially so if you have passed the same suture clear through into the peritoneum, and taken it up and out on the other side. It is possible to have infection, no matter how careful we are with our dressings after introducing the sutures. After applying what we believe to be aseptic dressings, in some way the infection will enter at the surface and extend downward to the deep fascia. I have tried to avoid this by using buried sutures and sterilized catgut, sterilized kangaroo tendon and sterilized silk worm gut, but I have had the same results in many instances wherever I had the suture coming to the surface, so that more recently, after using sterilized material, I have dressed the wound with an antiseptic dressing so as to prevent the entrance of germs from the surface, following up the suture and producing an infective center. Since I have adopted this plan, about a year ago, I have used silk-worm gut—have not used catgut—and have employed silk, and have practically gotten rid of stitch abscesses. Whether this is because of better sterilization of the suture material, or because I put on antiseptic dressings, which usually consist of gauze dipped in equal parts of alcohol and water and 1 to 2000 bichlorid laid on the wound, I am unable to say.

In the hospital it is conceded by the staff that Dr. Boeckmann's gives better satisfaction than any other sterilizer that we have used.

I have been using the last year pyoktanin-catgut. By using pyoktanin it colors the catgut blue, and if the catgut is not entirely saturated and is white in the center, then it is not thoroughly sterilized. I have had good results from it.

One objection I have to chromicized catgut is that it is like a piece of wire, not easily handled, while the other suture material prepared by pyoktanin is soft and pliable, and I believe is better sterilized and becomes absorbed with less difficulty than chromicized catgut. I have found chromicized catgut remaining unabsorbed two months after operation, which is a thing we do not desire.

Dr. J. P. LORD of Omaha—I have noticed, where there has been suppuration following the use of silk worm gut or silk sutures, that where the wound is closed *en masse*, too much is expected of a single suture. Many operators put in their stitches half an inch apart in a wound of considerable size, and expect altogether too much of these sutures. When inserted in this manner, they include a great deal of tissue and are necessarily tied very tightly, and I believe this to be one of the most fruitful causes of suppuration. I made this observation in watching Dr. Joseph Price this summer. He closed all his abdominal wounds in this manner, but the stitches were one-quarter of an inch from the margin, and not more than one-quarter of an inch apart. This made more thorough apposition than the same method observed by me in other hands. We should not expect too much of any one suture, and great care should be taken to make the tension uniform.

Dr. L. E. LEMEN of Denver—One reason why we have pus when we insert our stitches through the entire abdominal wall and include so much tissue in the stitch, is dependent upon pressure necrosis. With stitches put in after a clean incision, although we may not have any pus, and tied moderately tight, we have more or less engorgement or thickening of the tissues that produces necrosis, and we would not have this condition if we did not include so much tissue in our stitch. I have attributed pus in my cases to that.

Dr. W. J. GALBRAITH of Omaha—I do not believe it is possible for us to use any preparation of suture material without evil results, unless we consider the mechanical features in its application. All wounds, no matter how carefully and thoroughly we carry out our asepsis and antiseptics, contain more or less infective material. If a suture is applied too tightly, it causes strangulation, which is followed by inflammation and destruction of tissue, thus preparing a bed for the propagation of existing bacteria to develop to a greater or less degree. I believe more serious results are produced by the improper insertion of sutures than by the knife of the surgeon.

As regards the various suture materials used, with few exceptions, I rely entirely upon catgut. I believe it can be used to better advantage, and that we can secure better results with it than by any other one ligature, or all of the others combined. In the last month I saw one of our most noted surgeons in the country perform an operation, first using a reten-

tive suture of silk-worm gut, then a continuous suture for the purpose of securing and maintaining apposition of the skin, and at least one hundred stitches were used. I consider this radically wrong, unmechanical and unjustifiable.

Dr. W. W. GRANT of Denver—If I understood Dr. Boeckmann correctly, he made the statement that the only way to sterilize catgut was with dry heat. All surgeons do not prepare it in this way, and I have had so little confidence that my catgut has been thoroughly sterilized that I have confined myself to the use of chromicized catgut as prepared by Mr. Lister. I get it from London, and place it in a 5 per cent. carbolic solution shortly before using it.

Dr. N. SENN of Chicago—Since we have prepared our catgut according to the formula of Hofmeister, somewhat modified, we have done away with the evil results and have noticed no stitch abscesses. We regard catgut as absolutely reliable and aseptic, as has been proven by extensive practice in a number of hospitals throughout the United States.

Hofmeister, who has done such excellent service in perfecting the formalin preparation of catgut, gives the following most recent method: 1, the catgut is wound on a glass plate with slightly projecting edges, so that the gut is free from the sides of the plate and exposed to the circulation of the boiling and flowing water; the ends of the gut are fastened through holes in the plate; 2, immersion twelve to forty-eight hours in aqueous solution of formalin 2 to 4 per cent.; 3, immersion in flowing water at least twelve hours to free the gut from the formalin; 4, boiling in water from ten to thirty minutes. Ten to twelve minutes is amply sufficient, as all microbes and spores are killed by exposure to boiling heat for that length of time; 5, hardening and preservation in absolute alcohol containing 5 per cent. of glycerin and one-tenth per cent. corrosive sublimate.

The first attempts to sterilize catgut by this method under my own direction were made at the St. Joseph's Hospital by the Sister in charge of the operating room. The result of experience has led us to modify the procedure in several ways. Instead of glass plates ordinary abdominal glass drainage tubes have been employed, upon which the gut is wound quite tightly. These glass drains have been found an excellent substitute for the plates. An ordinary large test tube will answer the same purpose. The remaining directions given by Hofmeister were followed to the letter. Numerous inoculations with fragments of catgut prepared by this method in sterile gelatin invariably gave negative results. The catgut is as strong as the raw material, hard, and the knot is less liable to slip than when the ordinary material is used. We have also ascertained that the formalin catgut can be reboiled almost any number of times without impairing its strength.

Catgut to be safe should not only be absolutely sterile but should contain a sufficient quantity of efficient antiseptic to render it unfit as a culture medium for pathogenic microbes. Hofmeister renders it antiseptic by immersing it in an alcoholic solution of corrosive sublimate. Others have substituted carbolic acid for sublimate. Both of these antiseptics unduly irritate the tissues and increase the primary wound secretion, effects which can not fail in interfering, to a certain extent, with an ideal healing of a wound by primary intention. The valuable and interesting experiments made recently by Lauenstein leave no doubt that it is almost next to impossible to render the field of operation absolutely aseptic by any of our present methods of disinfection. We are forced to admit that nearly every wound inflicted by the surgeon's knife contains some pathogenic microbes, notwithstanding that the strictest aseptic precautions may have been carried out. The experiments made by Ewald have also furnished positive proof that sterile catgut contains a sufficient quantity of an unknown toxic substance which, by its destructive action upon the cells engaged in the reparative process, transforms them into pus corpuscles, resulting in the production of a limited aseptic suppuration and the formation of sterile pus. Undoubtedly many of the stitch abscesses which occur in the practice of painstaking aseptic surgeons have such an origin. These experimental researches force upon us the conclusion that catgut should not only be sterilized, but that it must be made sufficiently antiseptic to at least inhibit the growth, if not destroy the pyogenic microbes which enter the wound during the operation, or which may reach it later through the circulation. In this part of the preparation of catgut I have modified Hofmeister's method by substituting, for the corrosive sublimate, iodoform. After boiling the deformalized catgut for twelve to fifteen minutes, it is cut into pieces of desirable length, tied into small bundles, containing from six to twelve threads, when it is immersed and kept ready for use in the following mixture: Absolute alcohol, 950, glycerin 50, iodoform (finely pulverized) 100 parts. The alcohol dissolves part of the iodoform. The

bottle containing the catgut should be closed with a well fitting glass form, and should be shaken well every few days to bring the dissolved iodoform in contact with the threads. The catgut can be kept in this mixture any length of time without losing its strength. One of the valuable properties of iodoform applied to a recent wound is to diminish the amount of primary wound secretion. It does not destroy pus microbes but inhibits their growth. I have used catgut prepared by these modifications of Hofmeister's method with the most satisfactory results, and shall continue to use it until some better method is devised. (For a more detailed account of the method of catgut sterilization, see JOURNAL AMERICAN MEDICAL ASSOCIATION, Dec. 12, 1896, p. 1219.)

Dr. LEMEN—Have you had any difficulty with the iodoform decomposing and in having free iodine?

Dr. SENN—No. Until recently we used a 10 per cent. emulsion. Now we have made it a little weaker because the Sister claimed that it impaired somewhat the strength of the catgut. But we have used catgut for six months immersed in a 10 per cent. emulsion without losing any of its material strength. I have my reasons for modifying Hofmeister's formula, because I do not believe that the use of aseptic catgut will furnish us the ideal material. I desire to have absorbable material that is not only aseptic but antiseptic for the purpose of eliminating both the microbes and the toxins of the microbes, and I believe it is this addition to the preparation that renders the catgut far more reliable. It is the iodoform that keeps the wound dry, that furnishes one of the conditions favorable to ideal wound-healing—a dry wound, at the same time, it is an active agent in counterbalancing the ill local effects of preformed toxins.

Dr. BOECKMANN—I did not say that catgut could not be sterilized in any other way than by dry heat. I did say, however, that we know almost to a mathematical certainty the effect of dry heat, and that if catgut is properly sterilized according to the rules laid down by bacteriologists, it is thoroughly sterilized. I have seen in reports from Germany and other countries that they have found bacteria in every kind of catgut that has been prepared in a chemical way, as well as by dry heat.

I am convinced that Dr. Senn prepares his catgut in the right way: that it is sterilized, not by boiling, but in formalin, which is one of the strongest germicidal agents we have.

TRAUMATISMS OF THE CONTENTS OF THE ABDOMINAL CAVITY.

Presented in the Fourth Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Oct. 6-8, 1897.

BY J. P. LORD, M.D.,

ASSISTANT SURGEON UNION PACIFIC RAILWAY,
OMAHA, NEB.

When we turn our mental skiascope in retrospect, so as to reveal the dark places or shadows in the history of surgery, we are surprised to find that little more than a decade has passed since stab and gunshot wounds of the abdominal contents have been treated intelligently from a surgical standpoint. In these cases there was a wound of entrance and perhaps a wound of exit also, with perchance other and undisputable evidence of penetration of the organs within. Yet, notwithstanding these indications for operative interference, surgeons had continued for many years to ask the question so strikingly put by Abernethy, who asked, "is it enough that we examine the little hole made by the bullet, and as Nature, who shakes her head and leaves the patient to his hopeless fate?"

With the development of abdominal surgery, after the introduction of antiseptics, came the solution of the question. When, at the present day an advocate of any course other than that so generally adopted could not gain a respectful hearing. Slow as the profession has been to adopt radical surgical measures in the class of cases referred to, slower still have we been to adopt this course, in rupture from contusion, because of the absence of the same well defined evidence of visceral injury. These latter cases, which

are more in the province of the railroad surgeon, especially commend themselves for our consideration and discussion, because there can be no condition affording such amplitude of uncertainty as these. With the accumulation of cases and records of clinical observations we find our symptomatology uncertain. Hence the wisest acumen and profoundest judgment are required to guide the surgeon in his course, in the treatment of these frequently obscure, always grave and perplexing cases.

"Traumatism of the contents of the abdominal cavity" is so large a subject that the symptoms, diagnosis and operative technique can receive but brief consideration, so that it shall be my province to discuss briefly the indications, contra-indications or limitations of operative interference and treatment in cases of subparietal contusion, rupture or laceration of the contents of the abdominal cavity, rather than try to cover the very large field indicated by the title of this paper.

The recent text-books on surgery, works on abdominal surgery, journal articles and the opinions and practices of operative surgeons may be said to be unanimous in recommending radical surgical procedures, which can not but be regarded as the most judicious conservatism.

The stomach may receive varying degrees of injury from the receipt of kicks, blows, falls, squeezes, etc. Contusions may be received which may amount to only a temporary soreness, aside from the transitory shock invariably experienced to a greater or less degree, but usually this symptom is more marked when the stomach receives the injury than that produced by the receipt of a like amount by any other abdominal organ. This symptom may be so variable, however, as to be a poor index to the amount of damage actually sustained. A severe contusion, therefore, should be treated with the greatest circumspection; the patient should be compelled to remain in the recumbent position and all food or fluid by the mouth withheld, for the purpose of putting the injured organs at perfect rest, to permit of early resolution and repair, and as a precaution against secondary perforation in case of gangrene of the stomach walls, and also to mitigate the evils of rupture if it be actually present.

These cases are always of sufficient import to require the co-operation of the consultant. The general practitioner, especially, should forearm himself by calling the surgeon to his aid, just as he should do in case of appendicitis, so that the moment the emergency arises an operation can be done without the usual delay so fatal to an unnecessarily large portion of abdominal injury cases of all kinds.

The writer takes a strong stand for operative interference just so soon as symptoms point to probable rupture, barring shock bordering on collapse. Patients in a state of collapse should be rallied from this condition if possible, with a view of a more favorable opportunity to intercept, if possible, inevitable fatality. For, unrepaired ruptures of any considerable degree, of either stomach or bowel are probably always fatal. The prognosis, therefore, of this class of abdominal cases is worse than that of other forms of injury to the hollow viscera. It exceeds in mortality that produced by gunshot missiles of the largest caliber.

To enable us to cope more successfully with these desperate conditions, we should be better equipped

for treating shock and limiting its influence to a minimum. The hot water table, mattress or pad heated by an electric current is not enough. The extremities should be enveloped by some super-heated appliance to raise the body temperature: at all events, an efficient means should be made immediately available, to eliminate this fault, the need of which is almost universal.

With the more extended use of intra-venous saline injection, a distinct advance has been made in the successful handling of desperate cases, counteracting to a considerable degree the effects of hemorrhage, mitigating the severity of shock, reinvigorating the vital functions and contributing to the vital resistance. When we have added to these means a better knowledge of shock and improved methods of its treatment, we may limit the disastrous effects. This accomplished, earlier operations better borne, will lessen deaths from the second factor, septic peritonitis. Clean, judicious work in patients able to withstand the added shock, does not in itself decrease the patient's prospects. Closure of rents in the stomach or bowels by the most expeditious methods is imperative. Rather bring the wounded viscus outside the abdomen when practicable, or pack and drain, than to violate this injunction to provide against extravasation of visceral fluids. The stomach contents not being so septic as bowel excreta, rather more chances may be taken with the last named methods in dealing with the stomach than the bowel. Then, too, in the former it may be practicable to evacuate and cleanse, thereby lessening the danger in the use of this method. Though many bowel ruptures can be quite readily treated by leaving them outside the abdomen, when the same treatment of some wounds of the stomach may be quite impossible. If life is temporarily spared, much may still remain to be accomplished before the patient is made well. It must be remembered that nutrition is disastrously affected when the upper bowel empties outside the abdomen.

After rupture of the liver, gall bladder or bile ducts from contusion, there is not the same urgency for operative interference, unless it be for the arrest of hemorrhage, in which case the ligature, cautery and gauze tamponnage must be our reliance, to be used as required. Operative interference, however, after severe contusion about the liver, with symptoms to justify, should not long be delayed, for even though not septic the bile may be capable of much mischief. Suture of the gall bladder is indicated where practicable, which should be fortified by drainage. Gauze will answer in simple cases, but drainage by the gauze covered tube, together with judicious gauze packing, should meet the indications, and is probably all that is practicable to do where the cystic or common ducts are involved.

As to the diagnosis of rupture, Bryant says, after recently quoting five cases: "It must be confessed there are no special symptoms which can be accepted as indicative of its existence, although severe shock and collapse as immediate result of a forcible injury to the right side of the thorax should always suggest its probable existence, and even when the same kind of injury to the same region is unattended by any such serious symptoms the surgeon should be alive to the possibility of a limited rupture of the liver being present, and treat the same accordingly."

The spleen is especially vulnerable to injury, because of its friable nature and its bleeding quali-

ties. The organ should be saved if possible, but in case of necessity it may be partially or wholly removed, with less danger to the economy than under any other circumstances.

The pancreas may sustain sufficient injury to require ligation of its vessels, or its substance, together with partial removal. Gauze tamponnage may be sufficient in rupture of moderate extent.

Rupture of the mesenteric or omental vessels, causing free hemorrhage, can be treated intelligently in one way only—by celiotomy. After removing the blood from the abdomen, a forceps armed with gauze, introduced deep into the flanks and the pelvis, is likely to indicate the bleeding locality. The ligature is the remedy, but gauze may be required as a make-shift. Any considerable tear of the mesentery, parallel with the gut, necessitates resection of the latter, in the performance of which the shortest and best methods should be adopted. Intestine of questionable vitality should be left outside the abdomen if resection, for any reason, is contra-indicated. Exception may be made to this rule when the area of injury is small and in a loop of intestine near the abdominal incision, when gauze can be so placed as to isolate the questionable point and effect drainage in case of subsequent leakage.

Ruptured kidney requires exploration by abdominal or lumbar incision, for control of extensive hemorrhage, which is indicated by marked collapse and swelling. Excision should only be performed when the hemorrhage is uncontrollable and the presence of a second kidney is ascertained. Even moderate hemorrhage may demand nephrotomy for hydronephrosis and to clear the pelvis or ureter from an obstructing blood clot. Extensive laceration of the kidney may heal kindly; it being very vascular, repair takes place quickly. Gauze packing and drainage suffice in the majority of cases. Cystotomy is likely to be necessitated for the removal of blood clots from the bladder. In this the median perineal operation has the preference. Independent of other conditions, unilateral kidney injury has a favorable prognosis. Mr. Harrison says that "laceration of the kidney is a lesion more commonly recovered from than any corresponding one of an internal organ."

Absolute rest in bed, local application of cold, internal administration of opium and astringents—chief among them ergot—are the means to be employed in checking hemorrhage. The immediate repair of the ureter is indicated, but the diagnosis of torn or ruptured ureter can not usually be made until sufficient time has elapsed to produce the extravasation tumor; at which time the altered tissues prevent ideal treatment, when we must be content with tentative measures. Incision and drainage through the loin would seem to be the most practicable. Repeated punctures have been successful but not always. Secondary complications may require such surgical treatment as may be necessitated by the varying conditions. The surgery of traumatism of the ureter has not been extensive. Sufficient data is therefore lacking from which lines of treatment may be established, but I have confidence that our highly perfected art will soon have greater achievements to its credit in this as in all other lines of surgical adventure. The bladder, ruptured through the peritoneal portion, requires repair as soon as a diagnosis is made, for peritonitis and uremia are imminent dangers, ensuing in twelve or twenty-four hours. The diagnosis should present

no difficulty. The Trendelenburg position much facilitates the operation of repair. Lembert sutures or a modification thereof answers well the purpose, though the purse-string suture of Tait is probably quickest and best if the rent is not too great. Drainage is the rule and is a wise precaution. Frequent catheterization for several days should not be neglected. The peritoneum should be dried with gauze. Saline transfusion should be the rule, to favor the elimination of urea absorbed by the peritoneum. Summers of Omaha reports the speedy onset of uremia, after leaving a quantity of salt solution in the peritoneal cavity, in a case otherwise favorable for recovery. It was thought that the sudden large dose, following the rapid absorption from the peritoneum, overwhelmed the kidneys. Leaving salt solution in the peritoneal cavity would, therefore, seem to be a contra-indication in these cases.

The surgery of the thoracic duct may be said to be still in its infancy. Little more than tentative measures have as yet been accomplished.

Rigidity of the abdominal muscles, with marked restlessness and pallor, though variable in degree, are strong diagnostic indications of visceral rupture, more especially so of the stomach and liver. Constipation, though usually present in bowel rupture, is not to be relied on, and is practically worthless as a symptom in these days when a diagnosis must be arrived at in a few hours, rather than in a few days.

Operative interference is contra-indicated in traumatism of the abdominal cavity, in severe shock, unless to control hemorrhage. Never operate when the patient is in a condition of collapse or cyanotic from peritonitis and heart failure. General peritonitis from bowel rupture is nearly always fatal, but a few recoveries after operation have been reported.

The sooner rupture of the alimentary canal or urinary bladder is operated upon the better. The proportion of recoveries decrease rapidly after six and are usually hopeless after twenty-four hours. Indeed, most of the cases succumb in from twelve to forty-eight hours. The surgeon should have his inspiration before he gets his case, for there is no time for vacillating afterward. He should be prepared for action.

The railroad surgeon is in the service of two masters, which position always calls for the greatest circumspection, and especially is this true of our relation to railroad cases. But when we remind ourselves that in serving the best interests of our patients we are also doing the highest and best service for the railroad our course is plain.

Unnecessary and hopeless risks should not be taken in unwise zeal to render service. But humanity and duty require first consideration to our patients, an implied obligation required and expected by our employers.

DISCUSSION.

Dr. T. J. REDLINGS of Marinette, Wis.—I feel that I have been too conservative in the treatment of this class of cases and believe that Dr. Lord has outlined the proper limitation of precautions.

Dr. R. HARVEY REED of Columbus, Ohio—Dr. Lord has pointed out many conditions of the abdominal cavity arising from traumatism that baffle the railroad or any other surgeon to diagnose until the case has reached a serious condition. I recall a case in which a party was struck with a lath on the abdominal wall without even lacerating the skin, simply making a little red mark. The man was a large, muscular individual. He walked to his home, some four or five blocks, after the accident, and feeling badly he sat around the house for a short period, then went to bed and by and by what was termed

peritonitis set in. On examination I found a rupture of the intestine just as if the corner of the lath had struck it, tearing a triangular hole. This was done without laceration of the skin, fat or muscular tissues of the abdominal wall. I have seen two or three cases very much like this, but this was the most marked of the three in which there was no laceration of the abdominal wall, and yet there was severe injury of the intestinal tract. I advised operation at once, but some of the attending counsel thought it was unnecessary; that the condition was simply due to a bruise, and that the operation would not be of any advantage. After a little while the patient became worse and an operation was insisted on. On operating, we found the condition I have already described. Now, suppose it had been a railroad case and the railroad surgeon had been called in, the legal point would have been of great importance to the railroad, yet very excellent counsel had charge of the case and were unable to satisfy themselves that there was a tear of the small intestine, and it was surprising to find that the bowel, which is so movable and easily pushed from one point to another, should be torn by this force from the outside, without tearing the abdominal muscles. I can not account for it, but I know it to be a fact, and the patient died from peritonitis, extravasation and septic infection.

What are we to do under such circumstances? I think with the advantages of aseptic and antiseptic surgery, that where we have a doubt in our minds as to traumatism we are justified in making an exploratory incision to determine what is the matter at an early stage and not wait until the condition is such that we are unable to meet the complications that have arisen.

Dr. W. W. GRANT of Denver—What were the symptoms or evidences that called for an exploratory incision?

Dr. REED—In this particular case there was not the extreme shock that we would expect, but there was constipation. There was no action from the bowels from the time of the injury until I saw the man three days later. Where we have constipation following an injury of that kind, supposed to injure the bowels in a patient who is physically well otherwise and has been having action from the bowels every day, it is one of the points we should seriously consider. A little later we had a slightly increased temperature, followed again by a temperature a little below normal, but neither one sufficiently high or low to attract attention from the temperature standpoint. But I am always suspicious if I find a high temperature in a healthy man dropping a little below normal after an abdominal injury. Furthermore, we had in this case the physical fact that the man had been struck a terrible blow. He was an unusually strong man with great physical resistance which enabled him to walk three or four blocks to his home after sustaining the accident, and then there followed a condition which necessitated his going to bed. There was pain, lassitude and general depression. It seems to me these symptoms, following inside of twenty four hours after the accident, were sufficient to warrant a surgeon in making an exploratory incision, when there was nothing else to account for the condition; he was perfectly well when the accident happened.

I recall another case in which a person was shot five times in succession through the abdomen, every bullet passing through with the exception of one which was taken out of the skin of the back. That man did not have any particular shock. He, like the other patient, walked four blocks to his house, laid around for three or four days without any particular change in temperature and had no particular pain, and in a few days he was well and working again. Here was a case that I am unable to say what happened in the abdominal cavity, but evidently these bullets passed through without perforating the intestine. On the other hand, we had no perforation of the abdominal parietes, but we had the symptoms which would indicate that there was a serious injury to the abdominal tract.

Dr. W. J. MAYO of Rochester, Minn.—In order to widen the scope of the discussion, I wish to speak of those cases first seen more remotely from the time of injury, and particularly of those in which free fluid is present in the abdominal cavity. I recall the case of a boy, who was run over by a wagon and injured in the region of the liver. After a couple of weeks I found the boy was only moderately sick, with a temperature of 102 degrees, but he had a well marked ascites. The abdomen was drained of a large quantity of bile. The boy fully recovered.

The second case was that of a man of 40, brought into the hospital four days after receiving a severe contusion of the abdomen. He was obstinately constipated, had a temperature of 102.6 degrees, but a good pulse and looked well. After considerable effort his bowels were acted upon. About the sixth day ascites began to develop, although the general condition steadily improved. The free fluid slowly disappeared and in the course of six weeks he fully recovered. Just what the cause

of the fluid was in this case can only be surmised. I was careful to keep him very quiet and put him on a liquid diet during the second week, when, as experience has shown, a contused intestine is so liable to undergo secondary perforation.

The third case was one of rupture of the bladder from great violence, and in which urine was present in the abdominal cavity many hours before drainage was instituted. There was no peritonitis. The man died, however, a week later from the effects of a crushed pelvis received at the same time.

In these three cases the tolerance which the peritoneum may occasionally exhibit toward injury was well marked.

Dr. FRED J. HODGES of Anderson, Ind.—I presume that it will be taken for granted that every logical-minded physician would inquire carefully into the previous condition of the patient, but when one is called to a man, and a history of the injury is obtained, it is not infrequent that one's attention is so firmly riveted upon it that he neglects going into the previous history of the patient. A recent case coming under my observation illustrates the necessity, however, of considering it from all sides. A man who was working on one of the construction trains, and had worked for at least a month before I was called to see him, had struck the handle of his shovel against the belly along toward quitting time on Saturday and felt very little inconvenience from it, except that the belly was a little sore. That night he was awakened about 10 o'clock by an excruciating pain. A local physician was called in and found him practically pulseless and suffering intense pain. I saw him at 4 o'clock in the afternoon. There were indications of peritonitis, with the man in a condition which forbade operation. The same evening he died. On the following day an autopsy was made, and a well marked appendicitis was found, with practically the entire appendix gangrenous. By inquiring into the history the night before, it was learned that the man had been having some intestinal disturbances for a week and a little elevation of temperature at night. Yet he worked through the course of the disease and up to within twenty four hours before his death from peritonitis. So that a case like this occurring in a man's practice will cause him to look more carefully into the previous history of all cases of injury than he might otherwise do.

There was one point in the paper with which I take issue, and that is regarding the method of ridding the bladder of clots. In a man of middle age or under, as the average railroad employe would be, I believe that the high operation, or high drainage of the bladder, to be preferable to perineal section, that it can be quickly made, the bladder easily emptied, and there is no subsequent danger of stricture, as in the lower operation.

Dr. W. A. WARD of Conneaut, Ohio—In connection with the point of obscurity in diagnosis, especially unattended with any outward signs, I was called to see a man who was kicked in the abdomen by a horse. Following the injury there immediately developed severe pain. This case came under my notice in pre-antiseptic days, and of course, an exploratory incision was not made. The man was immediately put to bed, although there were no severe symptoms aside from pain, for three or four days. The most careful examination failed to disclose any marks on the exterior; but the man died about the seventh or eighth day with symptoms of well marked general peritonitis.

Dr. W. W. GRANT of Denver—How to treat these cases after the diagnosis has been made is the important question. In cases of laceration with extravasation, to open the abdomen and close the rent is the proper thing to do as soon as possible, or after reaction is established. But the difficulty is to know when we have a laceration as distinguished from profound shock, due to blows upon the abdomen through their influence on the solar plexus. We have all seen cases in which shock has been profound without laceration. Our axiom in surgery today is that no one should operate if shock was profound. After reaction is established, then the surgeon should determine in a few hours, if possible, whether or not there is laceration of any of the hollow viscera, or whether there is hemorrhage or not. These are questions it is often extremely difficult to determine. In case of hemorrhage we do not now wait so long before tying the bleeding vessel and closing the abdomen, because hemorrhage will prove fatal if this is not done. If we open the abdomen, although the prognosis is grave, we may save a patient that would otherwise die. If we can arrive at some of the symptoms indicative of the condition, it is the important point in this matter. In case of extravasation of urine we will have septicemia very soon if we do not open the abdomen and close the rent. If the intestine is lacerated and the colon bacillus has found its way into the general peritoneal cavity, we are quite certain to have general septic peritonitis and death, and early operation is the only thing to do, and the patient loses nothing by running that risk. If, after reaction, we have evi-

dences of localized peritonitis or a subnormal temperature, indicating a recurrence of hemorrhage or a continuance of it, the abdomen should be opened and the rent found, if possible, and repaired. With the opening of the abdomen we have a means of flushing the cavity with hot water and saline infusion, which at first were not thought to prove beneficial in bringing about reaction in many of these cases.

Dr. JOHN E. OWENS of Chicago—We ought to bear in mind that excision of the kidney is not always necessary in cases of traumatism, because we can remove a portion of it and get good results. This is an absolute necessity where we have no reason to suppose that the other kidney is diseased. In some cases an exploratory incision for the purpose of examining and handling the other kidney, when it can be done, is justifiable practice. I have done this a number of times where I have had to operate on pathologic kidneys, when I was in doubt as to the nature of the other kidney, and when the question of removal of the damaged kidney came up.

In some cases I have been impelled to open the abdomen when I did not seem to be guided by the assemblage of symptoms, except rigidity of the abdominal walls. This is a constant symptom of perforations of the intestine and in injuries to the other abdominal contents.

There is another matter we should keep before us in considering the differential diagnosis, namely, rupture of the diaphragm. We should ever be on the alert, even when a case has gone along well, or indifferently well for several weeks, and I can save time by giving you a synoptical report of a case. I forget the manner in which the patient was injured, but he had general uneasiness, which subsided in a measure, so that the patient was comfortable most of the time, as a result of the ordinary methods pursued—rest, opiates and hot applications. In the course of two weeks or more (I am speaking now with approximate correctness from memory) he had a very severe pain in the stomach and bowels, confined to the upper half of the cavity. We thought he would die in a short time, but opiates and hot applications brought him around, so that the next morning he was pretty well again. This occurred after eating several articles of food that his friends brought to him. He was doing so well that he was allowed to get up on a wheel chair, and one night subsequently he had this intense pain again. We prescribed the same treatment, but he died within seventy-two hours. This man had also a fracture of the ribs; he had emphysema and pneumothorax. A postmortem examination was made and we found the whole stomach and a coil of intestine that was gangrenous in the pleural cavity. The stomach was considerably dilated, and all this had passed through a hole in the diaphragm through which I could barely introduce the ends of three fingers.

Dr. H. REINECKING of Sheboygan, Wis.—One important condition which is apt to follow these injuries as a remote effect, is a localized adhesive peritonitis and the gradual development of intestinal obstruction. I have seen two cases within the last year which illustrate this danger very well. The great danger in these cases lies in slow development. Constipation comes on so gradually that operation is deferred until too late, until there is amputation of the afferent portion of intestine and perforation. When these symptoms develop, perhaps months after the injury is sustained, they call for an early exploratory laparotomy.

Dr. C. K. COLE of Helena, Mont.—The case mentioned by Dr. Reed illustrates the fact that there is a very wide difference with reference to symptoms in cases of injury to the abdominal viscera, and would seem to indicate that there are cases where operative interference is not necessary, or at least the condition can not be appreciated so that one would be warranted in operating. While in the other, and I believe in most of the cases of perforations of the walls of the abdomen, we are warranted in making an exploratory operation. Dr. Lord mentioned, in connection with the treatment, the use of opium and referred to the fact that Dr. Summers of Omaha left a saline solution in the abdominal cavity. As a rule, we should not make use of opium in these cases. I believe that we should leave the abdomen as dry as possible after a laparotomy for any lesion.

Dr. W. J. GALBRAITH of Omaha—Two or three important symptoms have been overlooked in injuries of the liver.

As regards Dr. Lord's quotation from Professor Bryant of New York, in which he says that delirium and shock are invariably two of the principal symptoms, I beg to take issue with him, for in at least five or six cases that I recall to mind, with one exception where there was the complication of ruptured spleen, evidence of shock was not manifested in the least.

I remember the case of a brakeman who fell from the top of a train, striking on the broad bars on his right side, and during the examination he said that it "knocked the wind out of

him," but that otherwise he was all right and wanted to go home. Experience in this case prompted me to strongly insist upon the man remaining in the hospital, for he presented that peculiar pallor and uneasiness which we may regard as one of the objective symptoms of rupture of the liver. After receiving the injury he walked six or seven blocks to the hospital without any aid, and in company with one of his friends, who had telephoned me that they would like me to see the man and make a report. He was put to bed and kept quiet. On the following day there was a slight rise in temperature with increased uneasiness and that peculiar pallor which is indicative of shock, but without the other symptoms. At the end of four or five days there was slight tympanites, increased uneasiness bordering on delirium, and about the sixth or seventh day he died. Autopsy revealed a very extensive laceration of the left lobe of the liver.

Another case was that of a lady, 22 years of age, who was in a railroad wreck about a year ago. She received injuries without any apparent external evidences. I saw her three or four hours after the accident. She was sitting in a chair and was one of the last patients to be examined. I asked her if she was hurt, and she replied, "nothing to speak of," but felt a little sore in her back and a little bit nauseated. She was in the room with several other patients, and my attention was directed to her by the beginning peculiar uneasiness which is so characteristic and certain in these cases. She would sit in one position, then move to another chair, and as time went on the peculiar pallor manifested itself. She was admitted to the hospital at Omaha on the day following the injury. No evidence of any peritoneal irritation or inflammation could be found. The bowels, bladder and all secretions, as I remember, were normal. The following day there was a slight decrease in temperature, but all the time this increase and progressive uneasiness associated with the characteristic pallor that I have seen in every case of rupture of the liver that I have dealt with. On or about the fourth day she began to complain of pain in her head and of slight pain through the thoracic and abdominal regions. At first, there was only mild delirium, which increased as time went on. Repeated examinations, both manually and bimanually, with inspection of the abdominal regions and other parts of her economy, were undertaken by my colleagues. I diagnosed rupture of the liver. She died about the ninth day.

In the presence of fifteen physicians, an autopsy was made by Professor Crummer of Omaha. I was the only surgeon who had entertained the idea that rupture of the liver existed. Much to my humiliation, after the liver had been placed upon the table and many sections made through its lobes no rupture could be found. The balance of the thoracic and abdominal organs were removed, but nothing abnormal was found. Dr. Crummer at this time proposed that we open and explore the brain, believing that some lesion there had caused death. However, I was not satisfied with the apparently careful examination of the liver. I placed it on the table, and asked the doctor to make a few openings into the liver. There was, as I remember now, in the right lobe near the center, a space some three inches in width, and the left lobe of the liver was left intact. The characteristic discoloration, which was slight, prompted me to make an incision at this point. The first cut, extending through as described, opened up a cavity containing about four ounces of clotted blood, showing that the liver had been ruptured and that my diagnosis was confirmed.

Another point concerning these cases is as regards the cause of this rupture. While, in a measure, we may state that ruptures of the liver are traumatic, how did the trauma occur in this case? There was not the slightest indication of any external violence, and in all other cases I recall the same condition existed.

I note the case spoken of, in which the man was hit by a lath and a triangular rent made in the small intestine. I do not believe these cases are the result of direct traumatism. Certainly no trauma was applied in the case that I have just reported. I believe these ruptures are due more to muscular action than to any other cause.

Dr. LORD—Authorities agree that a full stomach, or knuckle of bowel, which is so placed as to receive the injury, will rupture with slight force, so that the history and the amount of injury can not always be relied upon as showing the true condition of the case. Slight injuries sometimes produce disastrous results, but I think the rule is that considerable force has been applied in these cases.

Dr. Reed spoke of constipation as being a symptom in his case. I find in looking over the reports that constipation can not be relied on. While it may be rather commonly present, yet, in many cases, examination either during an operation or at the autopsy table has shown that quite extensive ruptures

have existed in the small intestine, and have not interfered with the action of the lower bowel, so that I think very little reliance can be placed on that.

In the cases of severe abdominal contusions which I have witnessed, there has been one symptom which is quite frequently noted, namely, inability to urinate, or symptoms of irritation referable to the bladder. In one of the cases I have seen there was momentary shock, but the patient suffered comparatively no inconvenience, and made a thorough recovery.

A rupture of the hollow viscera is very much more fatal than gunshot injuries. Many gunshot wounds are inflicted by instruments of small caliber, and such injuries may produce only a slight opening in the intestine, so slight indeed that the pouting of the mucous membrane is such as to completely occlude the aperture and prevent disastrous consequences, a plastic localized peritonitis being sufficient to cut off any escape of the contents. In dealing with these we can not treat them with the same "let alone methods" that we can cases where there is a wound or evidence of penetration.

One gentleman, in speaking of the method of relieving blood clots from the bladder in cases of rupture of the kidney, suggests that the suprapubic operation is preferable to the median perineal operation. The reason why the latter method is so regarded by most writers is because it affords drainage. Clots do not form; they pass out of the bladder as they accumulate. The median perineal operation is a comparatively simple one, and a drainage tube may be introduced which will carry off the clots and prevent their accumulation. While the suprapubic operation may be just as safely performed, although I am hardly willing to grant that, yet the complications, which afterward arise, in keeping the bladder clear of accumulated clots, would be evident, and I think that is the reason why the suprapubic operation is not regarded as highly as incision of the bladder with drainage. Other means may be used for evacuating blood clots, and if the hemorrhage can be arrested in the kidney, temporary removal of the blood clot might suffice. Breaking up the blood clots by instruments and withdrawal with an evacuator may be a preferable procedure. It has been suggested, also, that solutions of pepsin may be used for this purpose.

I think the point of determining the presence of a second kidney is a wise one. I saw the report of a case, by Phelps of New York, published in the *New York Medical Journal* quite recently, where a nephrectomy had been done for extensively lacerated kidney. The man died, and autopsy revealed the fact that the man had no other kidney. This occurs so frequently that it is well to be guarded before this operation is resorted to.

SOCIETY PROCEEDINGS.

Illinois State Medical Society.

Abstract of the Proceedings of the Forty-eighth Annual Meeting, held at Galesburg, May 17, 18 and 19, 1898.

The Society met at the Court House under the presidency of Dr. J. M. G. CARTER of Waukegan.

Prayer was offered by the Rev. W. H. Geistweit. An address of welcome, delivered by the Hon. F. F. COOKE, Mayor of Galesburg, was responded to by President Carter. After listening to and disposing of the reports of the secretary, treasurer, committee on publication and of various committees, Section 1 on Practice was called to order by the chairman, Dr. Arthur R. Edwards of Chicago; secretary, Dr. Frank P. Norbury of Jacksonville.

Dr. FRANK P. NORBURY of Jacksonville, read a paper entitled

MALNUTRITION IN INFANTS,

in which he said that the problem *par excellence* of an infant's life was that of nutrition. This was of great importance, as the days of infancy were dependent upon the ability of the infant to receive and assimilate nourishment. Nutrition was a physiologic chemico process which had for its object the supply of materials necessary to maintain the human economy in a state of health and to provide for its growth and development. Most all cases of malnutrition were the result of gastro-intestinal disorders incidental to errors of diet. Over-education of the mother was responsible for her lack of ability to supply wholesome milk to the infant. Again, other conditions, such as excitement, worry, neurasthenia, the occurrence of menstruation or gestation, may produce unfavorable results upon the milk and thus disturb its nutritive value. Artificial feeding in a great many cases was responsible for indigestion in infants. This was the result of faulty methods of administration of

foods and of the promiscuous and heterogeneous selection of food stuffs, prescribed by the neighbor or parent. The treatment had two main objects in view: 1, to arrest wasting; 2, to repair the damage done by the disease.

INFANTILE SCURVY, WITH REPORT OF CASES.

This paper was read by Dr. ISAAC A. AET of Chicago. He said the earliest reported of these cases were erroneously described as cases of acute rachitis. Möller of Königsberg, in 1859, described his first case. In 1862 he reported two more cases, one of which came to autopsy. Bohn in 1868 described a similar case. The cases reported by various authors show a striking similarity with reference to the symptomatology of the disease. He said we were indebted to Cheadle of London, who described the disease in detail as infantile scurvy in 1878, and later as osteal or periosteal cachexia with scurvy. He then cited cases that had come under his observation to illustrate the course of the disease. Its etiology was discussed at length, as well as the symptoms pointed out.

The diagnosis, in well marked cases, was not difficult. With reference to the differential diagnosis, congenital syphilis could be excluded by the history of the case, by the absence of syphilitic lesions on the skin and mucous membranes. In congenital syphilis there was never a history of severe pain. The pseudo-paralyses of syphilis were nearly always limited to the upper extremities; the swelling was never so intense as in cases of infantile scurvy, and was more prone to occur on the epiphyses than on the diaphyses. Separation of the epiphyses occurred in both diseases. A spinal paralysis might be thought of, although in such cases there was neither tenderness nor swelling.

The prognosis, if the disease be recognized sufficiently early and proper treatment instituted, was fairly good.

As to the treatment, brilliant results were obtained by providing a suitable diet. Fresh cow's milk or mother's milk, beef juice, orange or lemon juice, fresh vegetables, mashed potatoes, recommended by Cheadle, were the most suitable articles of diet. The child should be placed under the best possible hygienic conditions; good ventilation should be provided for, and under favorable conditions of weather the child should be out of doors. Cod-liver oil by mouth or inunction was especially indicated, when the child recovered from the scorbutic condition, to aid nutrition. Iron should be administered in those cases where atrophy or anemia persisted. Vomiting, constipation, dyspepsia, diarrhea, must be treated by adapting the diet to the age and condition of the patient and by the use of appropriate drugs. Small doses of calomel, mercury and chalk, pepsin or bismuth, may be used as indicated. Care should be taken to overcome the constipation which was frequently present. For the swollen and bleeding gums a mild antiseptic and astringent solution should be used.

Dr. FRANK S. CHURCHILL of Chicago, followed with a paper on "Modified Milk," in which he discussed the laboratory method and home modifications of milk. He claimed that substitute feeding is the most valuable method for artificial feeding.

Dr. JAMES B. HERRICK of Chicago, read a paper entitled

THE DIAGNOSIS OF PLEURISY WITH EFFUSION, WITH ESPECIAL REFERENCE TO MISLEADING PHYSICAL SIGNS.

He first spoke of the importance of careful inquiry into the history of the case, and dwelt upon the fact that in some cases there might be an absence of pain and of cough, the clinical symptoms resembling those of a mild typhoid. In other cases the severity of the symptoms and the explosive onset would remind one of pneumonia.

Among the signs that might mislead, he mentioned the occasional inspiratory recession of interspaces and the decubitus upon the sound side. He regarded vocal fremitus as of relatively inferior value, because of the many conditions that might cause it to be retained even though there is a large amount of fluid. The importance of the sense of resistance was emphasized. With small amounts of fluid a careful examination should be made in the posterior axillary line just external to the angle of the scapula, for signs are often present here though absent elsewhere. Even with quite large effusions there is a triangular area of relative dullness above the line of flatness posteriorly. Here could frequently be heard quite pronounced bronchial breathing and well transmitted voice sounds.

The crucial test is exploratory puncture. With careful asepsis and with a knowledge of the anatomy of the thoracic viscera there was practically no danger. Negative results should not lead to the exclusion of pleurisy with effusion until circumscribed collections of fluid had been ruled out. By means of exploratory puncture bacteriologic and microscopic examination of fluid was made possible, throwing much light upon etiology, prognosis and treatment. Palpatory puncture, to

use Rosenbach's expression, may be of great value in the diagnosis of underlying tumor, and may be the only means of determining the presence of the thick fibrous plates that sometimes line the chest.

Dr. B. W. SIPPY of Chicago contributed a paper on

THE SIGNIFICANCE OF CERTAIN SIGNS AND SYMPTOMS IN
HEART INSUFFICIENCY.

He said that the diagnosis of heart disease concerned itself not only in determining the particular lesion and its cause but, what was often of greater importance, in what manner was the diseased heart capable of performing its function? The author then dwelt upon the anatomy of the heart. He considered briefly insufficiency of the left and right hearts respectively and then, at length, total heart insufficiency. The left heart may become crippled in various ways. Owing to valvular defects at the aortic and mitral orifices, increased work thrown upon the heart by heightened arterial tension, as in chronic interstitial nephritis, the left heart may become incapable of doing its share of the work. Dilatation, compensatory hypertrophy of its walls and damming of blood in the pulmonic circuit takes place. The two sections of the heart sustain each other in their efforts to carry on the circulation. The passive congestion of the pulmonic vessels occasioned by the insufficient power of the left heart may be overcome by the right heart. As long as the right heart remains competent, the left heart lesion is compensated, the systemic arteries are filled more or less adequately, the systemic veins are emptied normally. The chief outward manifestations of this condition, dyspnea and cyanosis, are due to the overdistended pulmonic circulation. The right heart may become diseased independently of left heart affection, in the same manner that the left heart may become diseased independently of right heart affection. Increased tension in the pulmonic circulation due to pulmonary emphysema, fibroid phthisis, disease at the pulmonic or tricuspid orifices, results in similar pathologic sequences noted in left heart affections, namely, dilatation, hypertrophy and final damming of blood in the systemic veins.

The urine in heart insufficiency is diminished in quantity, highly colored, of high specific gravity, and as a rule contains a trace of albumin. Albumin may be continuously absent. As long as the degenerative changes of a nephritis are absent, the quantity of albumin will remain a trace. The hyaline cast, red and white blood corpuscles and epithelial cells, may be present. A considerable quantity of blood in the urine may be due to a kidney infarct. Such is the urine in kidney of passive congestion. The quantity of urine excreted in heart insufficiency is dependent much more on the diminished arterial tension in the kidney than on passive congestion, and is of great prognostic value.

In heart insufficiency the overdistended cervical veins stand out more or less prominently and the presystolic wave may become greatly exaggerated.

Dr. J. L. MILLER of Chicago, read a paper on

THE SMEGMA BACILLUS,

in which he drew the following deductions: 1. Over the entire surface of the body and exposed mucous membrane, and especially on the genitals, bacilli are found which resemble, morphologically and in tinctorial qualities, the bacillus of tuberculosis. 2. From the external genitalia they frequently gain access to the urine, especially in women, and may be a source of error in the examination of urine for tubercle bacilli. 3. The smegma bacillus presents wide variations in size and form, thus rendering morphologic differentiation frequently impossible. 4. While most smegma bacilli are more readily decolorized by any of the solutions commonly employed, occasionally they possess equal or even greater resistance than the bacillus of tuberculosis. 5. Methods of decolorization, where acids alone are employed, are fallacious; acid alcohol or dilute alcohols, unless long continued, are equally unreliable. Better, but not free from error, is the use of absolute alcohol for at least five minutes. In ammoniac urine, however, such prolonged use of alcohol may also remove the stain from the tubercle bacillus. 6. Attempts to remove the fat or fatty acids from the bacilli by ether, chloroform or other solvents, fail to furnish us with a means of differentiation. 7. We must rely on means of excluding the smegma bacillus from the urine. It has never been demonstrated in the bladder, and apparently seldom involves the deep urethra; therefore, by cleansing the external meatus and withdrawing the urine with a catheter, we can exclude this possible source of error.

Dr. GEORGE F. BUTLER of Chicago, spoke of the untoward action of drugs, with especial reference to hypnotic and anti-pyretics.

Dr. S. A. MATTHEWS of Chicago, read a paper on "A Pharmacologic Study of the Action of Digitalis on the Mammalian Heart and Circulation."

Dr. HUGH T. PATRICK of Chicago contributed a paper entitled

REMARKS ON THE TREATMENT OF NEURASTHENIA.

He said that for the production of neurasthenia, as for the production of nearly all disease, two conditions were indispensable, namely: 1, A noxious agent; 2, a relative vulnerability of the organism or of some part of it. The ratio of these two etiologic factors might be called the etiologic index. In some cases the first effect, that is, the extraneous agent, would be very prominent, the organism itself being considered as normal. In others, the exciting agent would be exceedingly slight, the inherent susceptibility or instability of the patient being an essential causal condition. Each of these two classes of neurasthenia would naturally need radically different treatment. In the first, those in which the patient once possessed of a normal nervous system, which had simply been overstrained and overdrained, the important features of the treatment would be rest and recuperation. In the second class of cases, those in which an unstable nervous system of the individual was at fault, the treatment is essentially mental, and the best way of administering it is by systematic education. For such patients isolation and an initial period of rest might be very useful, but for the further treatment gradually increasing physical exercise and mental occupation would be necessary.

A number of illustrative cases were cited to show the different types and the gratifying results of treatment varied in accordance with the classification before indicated.

Dr. M. L. HARRIS of Chicago described a new device for obtaining the urine separately from the two kidneys in either sex, and exhibited the instrument.

Dr. GEORGE W. COX of Chicago followed with a paper on

STREPTOCOCCAL INFECTION.

The author briefly discussed the subjects of puerperal septicemia, erysipelas, phlegmon, diphtheria, scarlatina, tuberculosis, and reported several cases of streptococcal infection, which he said could be easily detected and as easily cured, if the proper means were employed at the proper time. A microscopic examination would confirm the diagnosis and Marmorek's serum would accomplish the cure.

Dr. WILLIAM M. CATTO of Decatur read a paper on

URINARY FISTULA.

Urinary fistula may be congenital or acquired. The latter was most frequently encountered by the physician, and was nearly always due to violence, more rarely to disease. The various forms of fistulae were mentioned according to their situation and the structures involved. The author closed his paper with a report of two interesting and instructive cases.

Dr. EMMA B. STANDLEY of Alexis contributed an interesting rhyme entitled, "My Name is Appendicitis."

Dr. GEORGE W. JOHNSON of Chicago read a paper on

OBSERVATIONS ON THE BLOOD OF TUBERCULAR PATIENTS.

These observations were made on patients in the advanced stage of the disease with cavities, and at times hemoptysis. As to the cause of the apparent anemia in tubercular patients, Cabot and others have found that it is not due to a reduction in the hemoglobin. The same authority states that in uncomplicated tuberculosis the number of red corpuscles remain practically normal. Dr. Johnson in his observations paid especial attention to the patient's physical condition as to cavities and hemoptysis. These observations were made just before meals, and no attack of hemoptysis occurred between the first and second examinations. The patients were up and out of doors most of the time during the day. The microscope was used to compute the blood count. Of thirty-three patients examined, all had cavities of various sizes and all had had hemorrhages or hemoptysis. Of these thirty-three cases, twenty-five were found to have leucocytosis, that is, the white cells ranged above 7500 per c.mm. The twenty-five having leucocytosis also showed cavities. Cabot and others state that there is always a leucocytosis when there are cavities and after hemorrhages. Nine of the thirty-three showed a red blood count of 5,000,000 or above, which Cabot states as a normal basis. The remaining twenty-four showed a red cell count, in many instances far below 5,000,000, and in no case was the hemoglobin up to normal. In only one case did it reach 75 per cent.

Having made observations to determine the character of the blood, he also made some therapeutic observations, using 5 per cent. nucleic acid, No. 2, in the first ten cases; 5 per cent. nucleic acid, No. 1, in the second ten cases; ferratin in six cases and heminol in five cases. The first ten were given 22 c.c. every four hours for twenty-four hours. The second blood observation in the first ten cases showed six out of the ten to have a still greater leucocytosis. The red blood count was practically unchanged. The hemoglobin showed an

increase of from 3 per cent. to 10 per cent. in those cases in which there was a leucocytosis. The second ten were put on the nucleic solution, No. 1, which is chemically pure and for hypodermic use. Thirty minims were given hypodermically every four hours for twenty-four hours. The second count in these cases showed the same condition as in the first ten, which were given the No. 2 solution by the mouth. None of the patients complained of any bad effects, but experienced a sense of renewed energy, the circulation being better and the appetite improved. The speaker has noticed repeatedly the splendid stimulating effect of nucleic acid in every case in which he had used it. In cases not tubercular he has had splendid results.

Five cases were put upon heminol, 15 grain doses being given every four hours for thirty-six hours. A second examination of the blood of these patients showed an increase in the number of the red cells in four cases. Three showed an increase in the number of white cells, and only two showed an increase in the percentage of hemoglobin. The blood of the thirty-three cases was stained and studied, and in but two cases was there found a poikilocytosis.

Dr. H. W. CHAPMAN of Whitehall spoke of an undescribed form of la grippe.

Dr. A. C. COTTON of Chicago talked upon the subject of infant feeding at home and abroad. He gave an interesting description of the different forms of infant foods which he saw in foreign countries during a recent trip.

Dr. L. R. RYAN of Galesburg read a paper on "A Positive Antidote for Strychnia." The contribution was the result of a good deal of experimental research. The antidote in question is leontin. He detailed his experiments upon animals.

Dr. C. C. HUNT of Dixon followed with a paper on

CHELIDONIUM MAJUS IN INOPERABLE CARCINOMA.

He stated that Dr. Denicenco first experimented with chelidonium in cancer of the lip, and having obtained good results he used it in inoperable cancer. Dr. Hunt had used it in three cases, and while he would admit that the action of the remedy as observed in them was not absolutely conclusive, yet the results appear to corroborate in the main the claims advanced by Dr. Denicenco. Dr. Hunt concludes that: 1, chelidonium majus, injected interstitially into the substance of a carcinomatous growth, tends to its obliteration by necrobiosis; 2, copious and frequent interstitial injections of the fluid extract are unattended with danger to the patient, if judiciously used; 3, in cancer of the rectum, even at an advanced stage, stenosis may be prevented and the necessity of palliative colotomy obviated; 4, it is a deodorizer of no mean power; 5, there is some warrant for the belief that it has a favorable influence over glandular infiltration and tends to prevent metastasis; 6, it is a hemostatic and antiseptic; 7, it gives the patient hope of ultimate recovery, and this tends to mitigate or annul the awful apprehensions of impending dissolution, apprehensions, we may well opine, more appalling than death itself; 8, more comprehensive and exact experiments are necessary in order to determine the real value of the drug.

(To be continued.)

American Medico-Psychological Association.

Fifty-fourth Annual Session held at the Southern Hotel, at St. Louis, Mo., May 10-13, 1898.

(Continued from page 1295.)

FIRST DAY—EVENING SESSION.

Dr. E. N. BRUSH read a paper by Dr. C. W. PILGRIM, entitled "Does the Loco Weed Produce Insanity?" The author, incited by a statement by a popular writer of fiction, had investigated this subject and reported an interesting case attributed to this cause, but which appeared to be rather due to specific infection.

The next paper read was by Dr. B. W. STONE of Nashville, entitled "Thyroids in Insanity." He said that his experience with this agent had been most favorable and that he would try thyroids in every case. He read reports of a series of cases of remarkable results of thyroid treatment including one of agitated dementia of over four years duration, nearly well at the present time. Ill success in treatment is often due to insufficient dosage. He had it carried up to 55 grains daily in robust men, had at times had alarming effects on pulse, etc., and thought it ought to be carried out only in asylums.

Discussion was by Drs. Burr, Bancroft (unfavorable experiences), Brush (ditto), Burgess (worthless except in some cases of stuporous melancholia, experience has simmered down to this). In one case of latent phthisis it probably killed the patient.

Dr. HILL suggested the subject might be one for inquiry by the Association. He had used thyroid from an early date and his enthusiasm still exists. He would think he had neglected his duty if he had not used it in some cases. He did not use large doses (7-15 grains sufficient), has made motor disturbances a guide, but has abandoned it in melancholia, perhaps because he did not use a sufficient dose. Thyroids decrease excretion of solids. He has experimented with suprarenal extract and found the opposite effects. How is it the loss of weight occurs? His pathologist, Richardson, suggests it is due to breaking up of hydro carbons into CO₂ and OH₂. A suggestion was made as to its value in diabetes and he reported a case in which in one month there was reduction of 63 grains of sugar with undiminished urine. Dr. Brush, reporting a contradictory result, added that three cases at Sheppard that were positively deranged were cases of diabetes.

Dr. MABON had used thyroids and found great results in stuporous cases.

Dr. BANCROFT asked about blood changes and what preparations were used.

Dr. MABON said that he was having blood examinations, but was not ready to report; he had used Parke, Davis & Co.'s preparation.

Dr. BUCKE had had lack of results.

Dr. HURD had had remarkable results in some cases, but in mental diseases he had not had good results with this remedy.

Dr. EDWARDS asked what was the effect on the thyroid gland itself.

Dr. STONE, in closing, stated that he had used both Armour's and Parke, Davis & Co.'s preparations. In all cases with improvement there was an increase of ruddiness, but he had made no special examination of the blood.

SECOND DAY—MORNING SESSION.

After miscellaneous business, reports of Finance Committee, report on candidates for membership, etc., had been attended to, the President called for the report of the Committee appointed on the treatment of the criminal insane. In the absence of the chairman, Dr. CHAPIN, Dr. H. E. ALLISON offered the report, the conclusions of which were as follows:

1. That medical officers connected with all penal institutions should possess an experience in a general hospital or should have manifested a fitness for the position by a successful general practice, and should have, in addition, some experience in the treatment of the insane.

2. The compensation for such services should be adequate to secure competent and well qualified men, and that the position should be a reasonably permanent one, dependent upon merit and efficiency and not upon political influence or personal preference; that the duties of such physicians be so defined by law that in the discharge of his professional work he can exercise an independent judgment and possess an authority sufficient to control his medical functions.

3. That there shall be kept at all prisons a record on admission of any mental or physical peculiarities, and that entries shall be made from time to time of any additional peculiarities or actions and that each case report shall be in permanent form.

4. That so far as practical, special hospitals for the insane form and at all times accessible to the proper authorities, criminals be erected as an adjunct to the courts and prisons, where the insane criminals may be transferred and therein detained, without regard to the length of sentence, until recovered or otherwise so improved in mental and physical condition for release.

5. That the attention of the National Prison Association be directed to this subject with a view to securing their co-operation in providing better facilities for the detention and proper custody of the insane in the prisons of the United States.

On motion of Dr. H. M. HURD, the Committee was continued and authorized to co-operate with the National Prison Association, and it was ordered that the report be published in the *American Journal of Insanity*.

Dr. C. P. BANCROFT, for the Committee on Nominations, reported as follows: President, H. M. Hurd of Baltimore; of Michigan; auditors, H. A. Tobey and C. B. Hull; council vice-president, H. A. Gilman of Iowa; secretary, C. B. Burr three years, L. C. Meade, C. W. Babcock, C. D. Page and L. P. Wade. These officers were elected.

Dr. HURD then reported on the *Journal of Insanity*, showing a balance of over \$500 on hand in cash and good accounts.

Dr. MURPHY reported for the auditors, and Dr. Burr on the proposed amendment of the constitution, making eligible for membership those who by their writings and qualifications in the specialty of nervous and mental medicine were considered worthy aside from any hospital connections. The reports were accepted and adopted.

Dr. C. P. BANCROFT read a paper on "Subconscious Homicide and Suicide; their Physiologic Psychology." He discussed at length the theories of consciousness and its aberrations and reported two cases occurring in apparently non-epileptics, in which homicide or suicide had been attempted in a state of suppressed or modified consciousness. Such cases of non-epileptic automatism were of the greatest psychologic and forensic interest, and he reviewed at length their possible explanations.

Dr. H. E. ALLISON next read a paper on "Insanity and Homicide." He explained the methods and results at the New York Asylum for insane criminals at Matteawan. The crimes of the insane are mainly against persons. They had there 398 cases with records of successful or unsuccessful attempts against life, and 24 per cent. of those given life sentences in the State were inmates of the criminal asylum. His paper contained statistics showing the ultimate relations of insanity and crime and some striking cases were reported. In conclusion he called attention to the following needs; special hospitals for the insane in connection with the courts and the penal institutions of our larger States; more thorough examinations by the courts, of the mental conditions of persons charged with crime; better methods of obtaining medical expert testimony; the granting of greater powers and authority to prison physicians; more extensive clinical records in the prisons; and the acceptance of the doctrine that dangerous lunatics should be confined until mentally fit to be at large.

Dr. B. H. HILL spoke of recent legal decisions modifying criminal practice in Iowa courts as an advance in the right direction.

Dr. BANCROFT's and Dr. Allison's papers were discussed by Drs. Tomlinson, Woodson, Harrington, Robinson, Eastman and Brush.

There was no afternoon session but the members were given a carriage ride through the city and parks, taking in the principal points of interest.

SECOND DAY—EVENING SESSION.

The annual address was delivered by Dr. J. T. ESKRIDGE of Denver, on

THE MUTUAL RELATION OF THE ALIENIST AND NEUROLOGIST IN THE STUDY OF PSYCHIATRY AND NEUROLOGY.

He spoke of the close alliance of the two specialties. The expert alienist ought to know something of everything in medicine and everything on psychiatry; he must necessarily be an expert neurologist. It follows that the study of mental ailments is the same in essentials as that of obscure nervous diseases. With the asylum physician it is especially difficult because the required history of the case is so often unattainable; were it not so, much would be clear that is now obscure and it is to the carelessness of the neurologist and general practitioner, in this respect, that is due much of the blame for the backwardness of psychiatry in this country. The speaker gave the essential points of the examinations and the requirements of a hospital. He dwelt especially on the examinations of usual as well as of emotional states, the condition of the memory, etc. Among all the hospital appliances were mentioned pathologic laboratories and their work, and a list of the institutions in which they existed were given. The neurologist is called upon to treat and care for many cases and phases of mental disorder and a practical knowledge of mental disorders is as useful and essential to them as is that of neurology to the alienist. It is only when the neurologist has become a practical alienist that he could greatly criticize the alienist. The neglect of training and instructions on mental disease in our medical schools was remarked upon as a cause of misapprehension and mistakes. A general plan of an ideal insane hospital was laid down in detail. The qualifications, duties and privileges of medical directors, assistant physicians, the proportion of the medical staff and attendants to patients, training schools for nurses, scientific associations, consultants, psychologic research, etc. The time would come when the recognizably best neurologists would be those who had had training in hospitals for the insane, and it is only in the combined and harmonious action of both alienists and neurologists that we are to look for real progress. A union of the Medical Psychological and the Neurological Associations was suggested as a proper end to work for in furtherance of the common aim.

The president presented to Dr. R. S. DEWEY, on behalf of the Association, a massive silver pitcher, in appreciation of his work in carrying on the *Journal of Insanity* for three years. Dr. Dewey responded, expressing his thanks.

Dr. ESKRIDGE presented the invitation of the physicians of Denver to the Association to attend the meeting of the AMERICAN MEDICAL ASSOCIATION there. Dr. Hughes endorsed this as chairman of the Neurological Section.

Dr. WOODSON offered the hospitalities of the St. Louis Club and of the public libraries.

THIRD DAY—MORNING SESSION.

The report of the Council was offered and report on members and ballots cast for those recommended by the Council. New York was fixed upon as the next place of meeting, the date to be hereafter arranged and notification by the Secretary. Committee of Arrangements: P. M. Wise, A. E. Macdonald, B. Sachs, and Frederick Peterson. The report was adopted.

Dr. MURPHY finished the report of the Auditing Committee.

The Committee on Training Schools reported progress and was continued.

For the Committee on After-Care of the Insane, Dr. Dewey stated that a report had been made to the Conference of Charities last year and arrangements made for continuing the work. The report was accepted and adopted. Dr. Brush was appointed to attend the Conference of Charities and represent the Association, in addition to Dr. Dewey.

The first paper of the day was by Dr. R. S. DEWEY, entitled SOME REMARKS ON THE RELATION OF MENTAL DISEASE AND SURGICAL OPERATIONS, WITH REPORT OF FORTY CASES OF INSANITY FOLLOWING SURGICAL OPERATION.

He, out of some five thousand insane, had met with eight cases of insanity following surgical operations in sound individuals, and many more in those with an insane or neuropathic taint. He presented a tabulated statement of forty-six cases, stating prior conditions, operation, anesthetic used, occurrence of shock, mental states following operation, duration of insanity, outcome of operation, etc. The class of operations followed by mental disorders were, in order of frequency, those on the genito-urinary organs, the eye and the mammary glands; operations on the brain were excluded, and with this exception the proportions of such cases in asylums was apparently not over 1 per cent. The sources of error in the statistics were discussed at some length, misunderstandings of insanity, the ignorance of surgeons on this subject and their lack of study. The importance of the surgeon giving careful attention to the mental state of the subjects of operation as a prophylactic of insanity was emphasized.

The paper was discussed by Drs. Hurd, Tomlinson, Bancroft, Russell, Bannister, Punton and Woodson.

Next followed a series of papers, all bearing on the care of the insane, which were read consecutively, the discussions being postponed to the last. The first was by Dr. J. RUSSELL of Hamilton, Ont., on

ASYLUM VERSUS HOSPITAL.

The paper was a well-written plea for more conservative methods as compared with the tendencies of the time to assimilate all the institutions for the insane to general hospitals, with their active operative tendencies and scientific examinations. He gave a historic review of the use of the terms asylum and hospital, and remarked that in the list of institutions for the insane in the United States and Canada there were ninety-three hospitals and forty eight asylums. The word "hospital" was a misnomer as regards institutions for the insane, and their evolution must be along industrial rather than hospital lines. Mental and physical activity is the note that must be struck in the care of the insane, control in some cases, arouse in others and in all restore their brain's normal activity on a physiologic basis. He gave his ideal of the twentieth century asylum, treatment by regulated activity, and with this increased recoveries, success and economy. It is the duty of the alienist to instruct how to produce and how to live. The paper closed with a plea for the mental and moral treatment of insanity as opposed to the physical or modern scientific medical treatment.

Dr. W. M. EDWARDS read a paper on "Some New Hospital Buildings." He described and exhibited plans of new additions to the Michigan Hospital at Kalamazoo, and advocated the use of detached buildings for recent and curable cases.

Dr. B. D. EASTMAN's paper on

STATE VERSUS COUNTY CARE FOR THE INSANE,

followed. After stating the present conditions in Kansas, he reviewed the question of State and County care in other parts of the country and gave especial attention to the contrasted methods adopted in New York and Wisconsin. He considered the Wisconsin claims excessive and held that this was confirmed by the report of the Pennsylvania Commission that treated of the subject, and analyzed the claims of the advocates of the asylum, Wetherill, Heg and others. The objections to the two systems were respectively: New York, care of the insane is too expensive, the institutions are too widely separated, there is less employment; Wisconsin, imperfect medical supervision, absence of classification, necessity of keeping all

the ill, feeble and dangerous cases in the State hospitals, lack of diversions, over-economy of rural authorities, lack of adequate inspection. The economy of the Wisconsin plan was, he thought, over-estimated. He summed up in conclusion, the advantages and disadvantages of each plan, and gave as his ideal system, State care in numerous small, well-equipped hospitals.

Dr. H. A. GILMAN's paper on "Better Care for the Chronic Insane" followed the same general line of thought. He objected to the plan of county care as introduced into Iowa. The lack of individual treatment was a great objection in these county institutions.

THIRD DAY—AFTERNOON SESSION.

Dr. W. B. LYMAN opened the session with a paper on

THE WISCONSIN COUNTY CARE SYSTEM.

He claimed that Wisconsin has a system peculiar to itself, satisfactory to its people, and one that solves the question of the care of the chronic insane. A description was given of the county asylums, their relation with the State hospitals, the methods of transfer, etc. A lack of the system was the need of accommodation for chronic dangerous cases. He advised the commitment of chronic patients directly to the county asylums, instead of through the State hospitals as at present. After describing the condition of the State hospitals, he enumerated the advantages of the county institutions. Open doors were the rule, 70 per cent. of the inmates were on parole and a large percentage of occupations. Wisconsin has fewer deaths from tuberculosis in its insane than any other State. Other advantages were, more frequent visits from friends, the general popularity of the institutions. The Board of Control had full authority and responsibility, and under their system persistent abuse could hardly exist undiscovered.

Dr. F. C. HOYT's paper on

OCCUPATION IN THE TREATMENT OF THE INSANE,

closed the series. He spoke of the advantages of rational occupation for the insane; it is the best method of preventing secondary mental degeneration, if employed under the careful and judicious oversight of the physicians and not of the lower grade of employes. The patient's own taste should be consulted; also his health and feelings. Open doors and paroled wards, if careful discrimination was not exercised, had a tendency to make idlers and hospital loafers; a parole should be earned by industry and good behavior. Speaking of occupation as a therapeutic measure, he thought it should be in small doses at the beginning and gradually increased till the full physiologic effects were obtained.

Dr. WOODSON, in the discussion, said he could not see the necessary connection between economy and small asylums, other things being equal; why should it cost less per capita in an institution with sixty or seventy inmates than in one with four hundred or five hundred. He described the night attendance at Fulton and the open dormitories. As regards occupation, he agreed thoroughly with Dr. Hoyt's paper. Abuses might occur anywhere but he had noticed that the public condoned them in a county asylum while condemning them in a State institution.

Dr. BURR said the Wisconsin asylum could hardly be called a success as yet. The real improvements are generally quite recent. The claims of economy and humanity were justified as regards the first element more than the last. He had visited the Wisconsin asylums in the winter time and had seen a lack of occupation and diversion, no books, pictures, etc.; that made the places dreary. It was admitted by the intelligent employes that the patients deteriorated in them. Among fifty-eight inmates of one institution there were fifteen with goiters, attributed by the visiting physicians to a lack of oxygen. The attendants were less watchful than he thought desirable, and while they claimed there was no trouble, he saw a patient with a black eye that looked suspicious. The nearness to home was sometimes an aggravation and was not a security against abuse. One official confessed to choking a patient as a disciplinary measure, and he heard stories of neglect, abuse and trouble. Political considerations were not entirely abolished in the management, and generally he had not found what had been expected from the claims made for the asylums. When the defects were done away with, the Wisconsin propaganda would be better justified, but not till then.

The papers were further discussed by Drs. Brush, Runge, Tomlinson, Gilman, Gordon and Gardner.

Dr. J. M. MAHON then read a paper on "The Value of Hospital Records," which was chiefly an exposition of a system devised for the New York State Hospitals, simple, thorough and labor saving, and which greatly facilitated the keeping of case records.

FOURTH DAY—MORNING SESSION.

The first paper read was by Dr. R. H. HUTCHINGS on "Practical Methods in Physiologic Chemistry." He described the methods used at Ogdensburg in the clinical study of the excretions, the blood, etc., and explained how, by the division of time and of the medical staff, this was made readily practicable.

Dr. A. H. HURD testified to the reflex value of this work on the staff and its influence on the patients who were led to take an interest in their own cases that aided in their treatment and led to a better feeling towards the physicians.

The paper was also discussed by Dr. HUGHES, who spoke of the methods as an antemortem pathology tending to more scientific practice and diagnosis; by Dr. W. O. KROHN, who described the psychologic investigations in Kankakee; by Dr. EDWARDS, who told of the methods in use in Michigan, and others.

Dr. BRUSH then read an outline of Dr. BABCOCK's paper entitled "A History of the Insane in America. Shall the Association have one Prepared?" He moved that an editorial and revisory committee be appointed for such purpose; that Dr. Babcock be appointed chairman, with authority to name his colleagues, and be directed to report at the next meeting of the Association. Carried.

Dr. A. M. GARDNER's paper on "The Insane in California," was then read. He mentioned the prevalent belief in the undue frequency of insanity in California, and gave the reason. State care was the system adopted, and he made a comparison with New York and Pennsylvania. The large foreign element in the insane was remarked, as shown for example in the Manhattan Hospital report. California has a predominance of foreign-born insane committed. The large cities and seaports are responsible for this, with the increase of urban population. Five-twelfths of the population of California is in the cities. More out of door agricultural life would improve the conditions. California is also the tramp's paradise, and these degenerates often find themselves finally in the asylum. The climate of California, by attracting the defective and degenerate, tends to increase the number of insane. Many of these immigrants err in their choice of residence in California, and this affects the figures. He mentioned the relation of tuberculosis to insanity, and said that its extensive introduction had already been felt in the increase of the insane. Narcomania was also more prevalent; the Chinese in introducing the opium habit had made a curse for the present and a danger for the future. With all this it could not be said that insanity was greatly increasing in the State; the commitments in 1898 were only eight in excess of those in 1886, which is an encouraging figure.

Memorial notices of Dr. GEO. ALLEN by Dr. TALCOTT; Dr. MOFFAT by Dr. GILMAN; Dr. McNARY; Dr. W. H. JONES by Dr. BEAUCHANT, and of Dr. OLMSTED by Dr. W. S. NOBLE, were read by title and referred to the Secretary, who was authorized to have them published in the "Transactions."

Dr. C. R. WOODSON's paper on "Some Forms of Syphilitic Insanity Resembling General Paresis," was next read. The author described certain types which he considered as indicating a difference between paresis and syphilitic insanity.

The paper was discussed by Drs. Runge, A. E. Macdonald, Hoyt, Gundry, Eskridge, Burr, and others.

The following papers were read by title: "The Nerve Cell Changes in Somatic Diseases," by Aug. Hoch, Waverly, Mass.; "A Short Study in Psychic Phenomena," by H. C. Eyman, Cleveland; "The Lesson Taught by a Few Hard Cases," by W. E. Dold, White Plains, N. Y.; "Hospital Treatment for Acute Insanity," by A. B. Richardson, Columbus; "The Boarding Out System in America. Why Not?" by G. Alder Blumer, Utica, N. Y.; "Incipient Melancholia—Its Diagnosis, Prognosis and Management," by John Puntun, Kansas City, Mo.; and "Experimental Mania," by T. J. W. Burgess, Montreal, Canada.

Dr. MACDONALD reported that he had represented, as commissioned, the Association at the British Medico Psychological Association and International Medical Congress.

Dr. BURGESS moved that Dr. Macdonald be delegate to the British Medical Association and British Medico-Psychological Association the coming summer. Carried.

Therapeutic Castration is the term applied by Rivière to the effect of thyroid medication in a couple of cases of arthritic obesity. The genital functions seemed to be suspended during the months of treatment, a phenomenon not noted before, but suggestive as extending the indications for the treatment to congested prostates.—*Semaine Méd.*, April 27.

Chicago Academy of Medicine.

Regular Meeting, March 18, 1898.

JAMES G. KIERNAN, M.D., in the Chair.

THE EFFECT OF PREGNANCY UPON TUBERCULOSIS.

Dr. C. E. PADDOCK—What effect has pregnancy upon tuberculosis? The usual answer to this question and the popular opinion is, that the result is beneficial; that the patient takes a new lease upon life. That this opinion is based upon good grounds is shown by numerous examples which any of us may recall. When we remember the changes which occur in the pregnant woman, it seems all the more plausible. We find an increase in the blood supply; the organs generally are more active; the skin becomes more hyperemic; the urine is increased in amount; the heart is enabled to meet the greater requirement which the condition demands. These changes are placing the woman in the best possible condition for the ordeal. In a tubercular pregnant woman we have emaciation, lowered vitality, anemia and every outward evidence of disease. The changes taking place, as enumerated, to prepare her for maternity, are unable to meet the requirements.

Normally, pregnancy is a physiologic process, but it borders so closely upon the pathologic that we are often called upon in the course of the pregnancy to give advice or treatment. For instance, the nausea, which occurs with such a regularity that it is largely considered in making our diagnosis as to the probability of a case of pregnancy. Ordinarily this does but little harm and yields to treatment. In a tubercular case, however, it is not so easily controlled, and in such cases has a very unfavorable influence. The woman's power of resistance would be lowered and the progress of the disease hastened. Not so much attention to this subject has been given as we would naturally expect, and our text-books hardly give it a thought. So far, scientific investigation does not aid us in determining the question as to the effect of pregnancy upon phthisis, and we must rely upon statistics and our personal experience.

In looking over the cases reported I find them about as this:

Case 1. Patient pregnant two months, anemic, poorly nourished, tubercular. Dies before child is viable.

Case 2.—Same as No. 1. Lives to deliver child at term, and dies in a few weeks.

Case 3.—Pregnant, missed one period, tubercular. No external symptoms of the disease. Child born at seven months, dead. Mother lives but a few days.

Case 4.—Pregnant two months. Emaciated, every external evidence of the disease. Gave birth to a vigorous child. Lives to become pregnant again, but succumbs to the disease.

Now, these are every-day cases which come to our notice, and these are the cases we find reported in looking up this subject, and are of very little assistance. I believe, ordinarily, pregnancy does exert an unfavorable influence upon tuberculosis. It is often unwelcome. The patient becomes morbid. Soon we have nausea with loss of appetite; the patient refuses to take proper exercise, and everything is favorable to the progress of the disease. Her power of resistance is lowered and the vitality is not sufficient to support two beings. There are cases which surprise us in every branch of medicine. Notwithstanding our unfavorable diagnosis, they recover. So also there are cases in obstetrics that are tubercular and accompanied by pregnancy which seem to improve. But these cases are rare. Where we find one of such we will find one hundred made worse by gestation.

Having a case of tuberculosis complicating pregnancy, what is the proper treatment to pursue? Shall we interrupt pregnancy or leave the case to nature? I report two cases in my practice:

Case 1.—American; 30 years; blonde; never robust, but always considered in good health; four children in five years, fifth pregnancy occurring six months after last child was born; dulness in right apex, no cough, slight evening temperature; abortion at second month after consultation, patient anesthetized, cervix dilated with Hegar's; curetted.

Following this, the patient seemed to have a little more temperature, there being a slight rise both morning and evening; seemed to take a mild typhoid course for four weeks; no pelvic trouble; recovered slowly and soon went to the seashore and White Mountains in apparently good health. After an absence of eight months she returned four months ago; both apices involved; sent to New Mexico; has received no benefit, and death hourly expected.

Case 2.—American, age 24 years; blonde; second pregnancy; active, apparently healthy and great endurance. Two months previous to second pregnancy glands in neck were removed;

tubercular; no other evidences of the disease. Pregnancy was complicated in the last month by hydramnios. A few months after delivery the patient left the city in apparent good health. Two years from date of delivery she died of pulmonary tuberculosis.

Case No. 1, I believe, was helped by the induction of abortion. I was enabled to institute treatment which would have been impossible in the pregnant state. In the second case the progress was certainly interrupted, but can we say that pregnancy was the cause of it?

In 1890 Dr. William Duncan¹ reported a case of interruption of pregnancy in a tubercular woman. This communication provoked a discussion which was, with but one or two exceptions, opposed to his line of treatment. Drs. Priestley, Routh, Playfair, Napier and others took part. Dr. Routh thought that most obstetricians had observed that the progress of lung destruction was at a standstill during pregnancy, but became very active during lactation. Dr. Playfair believes "that in the greater number of cases the mother is doomed, and everything should be done in the interest of the child. To say that pregnancy should be interrupted in any stage of phthisis and at any period in pregnancy is too broad a statement and gives too much latitude to the physician, and should not be tolerated." Cullen of Edinburgh asserted that phthisis in pregnancy was suspended or retarded, and such was the belief by others for years until M. Gaulard of France, took the other side and made the positive statement that there is no interruption in the progress of tuberculosis in pregnancy any more than there would be interruption of any other disease in the same condition. Dr. Priestley, in a paper read before the London Obstetrical Society in 1880, laid it down as a rule "that abortion was only a legitimate operation when the life of the mother was imperiled by the continuation of pregnancy, emptying the uterus presenting itself as the only alternative to save the patient."

What evidence have we that this does prove the only means of saving the woman? and again, if we do produce abortion, what excuse have we for not doing it again and again? Once in a great while we will encounter a case who lives a long time and, as these cases of phthisis for some reason conceive very rapidly, if we operate once we will be called upon in such a case to do so again. There is not evidence enough to warrant us in asserting that the interruption of pregnancy means a saving of the life of the mother, and neither can we justify such a procedure by saying that an inferior child would be brought into the world.

My case No. 1 is not unlike nearly every case I can find recorded. The case was only benefited temporarily. A fetus was sacrificed which might have developed into a healthy child, for not all children born of tubercular parents are themselves tubercular or puny. I can see no justification for such treatment.

My conclusions are based upon clinical facts as presented by others and upon my personal observation:

1. Pregnancy does exert an unfavorable influence upon tuberculosis in the majority of cases.
2. That the case is progressive and not arrested.
3. That only in exceptional cases, as in advanced tuberculosis with the child viable and mother about exhausted, are we justified in terminating pregnancy, and then only after a consultation with two or more reputable physicians.

GENERAL REMARKS ON TUBERCULOSIS.

Dr. ROBERT H. BABCOCK—We should regard pulmonary tuberculosis and consumption as somewhat different. The former is a pure and unmixed infection, which is amenable to treatment. It is in this stage of the disease, when the infection is unmixed, that we get our cures. Consumption is a mixed infection, and when this secondary infection has advanced to any considerable degree, the prospect of an arrest of the disease is bad. Our efforts, therefore, should be addressed to the recognition and treatment of pulmonary tuberculosis while it is still tuberculosis, and not consumption.

I was greatly interested in Dr. Paddock's paper concerning the influence of pregnancy upon phthisis, and agree with him fully that the course of the disease is unfavorably affected by pregnancy. I should go farther, however, and say that in my experience, although I have no statistics and have not had time to look up my records, pregnancy can be regarded as an etiologic factor in the production of pulmonary tuberculosis. Women with an hereditary predisposition to consumption, certainly in my experience, have the disease hastened and often developed while carrying the child. I have frequently observed cases, have in mind one now, in which pulmonary dis-

¹ Dr. Wm. Duncan: Trans. London Obstet. Soc. 1891, Vol. xxxii, Lancet, 1890, p. 134.

² Dr. Priestley: London Obstet. Soc., Vol. xxii.

ease developed within a few weeks after parturition, before the injurious influence of lactation could be manifested. I do not agree therefore with those physicians who recommend pregnancy to women of tubercular tendencies, on the ground that it will prove a physiologic tonic. They are too frequently in a state of lessened nutrition to stand the further drain made upon their vitality in nourishing their children, and in such an event pulmonary tuberculosis is very likely to supervene.

Hemoptysis is one of the symptoms of pulmonary tuberculosis which is justly regarded, both as a serious ooe, and also looked upon as a symptom that ushers in pulmonary tuberculosis. I shall briefly speak of two cases of hemoptysis that have recently come under my observation. One was a male who consulted me the day after he had twice expectorated blood the previous evening. Examination of his lungs was negative, although I was not altogether pleased with the findings in the right apex. He was sent to a throat specialist, who reported a large number of dilated veins in the pharynx, larynx, and far down in the trachea, some of which showed evidences of recent rupture. I believe this was a case of what Powell designates false hemoptysis, and that the patient was not tubercular, but to settle the question I gave him three diagnostic doses of old tuberculin. The result proved the correctness of my opinion, for none of these injections was followed by any reaction whatever. The second was the case of a female who had expectorated blood at intervals since December last. Examination of her chest was negative, except that at the left apex the respiratory sounds seemed to me not quite as vesicular as they should be. Her throat was also examined, with the result that some dilated veins were found at the root of the tongue. Three injections of tuberculin at proper intervals were given to this patient with the same result as in the other. There was absolutely no reaction, the temperature having been in this case, as well as in the other, taken regularly, and faithfully recorded.

These cases illustrate the importance of careful investigation of those cases which consult us because of hemoptysis, and a cautious opinion that they indicate the incipency of tuberculosis of the lungs before they have been sifted to the bottom, and the presence of the disease established, or satisfactorily shown not to exist.

The more experience I have with pulmonary tuberculosis, the more impressed I am with the fact that we are likely to meet with surprises. We not infrequently encounter cases of acute phthisis which are illustrations of acute, confluent, tuberculous bronchopneumonia, in which the patient loses strength and emaciates rapidly: the lung rapidly goes on to softening and excavation, and there seems to be every prospect of a fatal termination within a few weeks. At length, however, just as it seems the patient's strength can not hold out much longer, the lung begins to give evidence of a change for the better, the symptoms improve, and the patient ultimately develops a case of chronic phthisis, and under a favorable environment in a proper climate may even have an arrest. The cases which to my mind furnish an absolutely unfavorable prognosis from the start are those in which there is a disseminated peribronchial tuberculosis with secondary bronchitis. The persistent elevation of temperature; the paroxysmal and uncontrollable cough; the rapid wasting and loss of strength, all the symptoms, in short, are out of relation to the fewness of the physical signs observed. These are the cases which resist all treatment.

I have used Dr. Fisch's serum in six cases. In five the results have been highly gratifying. In one, a young man who came to me with hemoptysis, last July, and in whom there were signs of incipient disease of the left apex, bacilli were found in the very scanty sputum. This young man was placed upon the use of this serum in September last, and it alone, with the result that today the signs in the left apex have almost disappeared. In other words, the active disease process in that apex has disappeared, and there are only left the signs of the ordinary fibroid transformation which takes place in some of these cases. So gratifying was the result of treatment that about two weeks ago I decided to give him tuberculin for the purpose of deciding whether or not immunity had been established in his case. Two test doses were given without any reaction. A third test dose of ten milligrams of old tuberculin were administered, and for twenty-four hours there was no reaction whatever; then suddenly reaction took place, demonstrating that his system was not rid of the disease. Several careful examinations of his lungs, since then, have shown absolutely no irritation from the tuberculin in the former seat of pulmonary disease, and therefore I am forced to the conclusion that in his case there is glandular infection, probably intrathoracic, to which the marked reaction is to be attributed.

Another case was that of a man, whom I first saw last April, with disease of the left apex, and who, under ordinary consti-

tutional treatment, improved somewhat during the spring and summer, and reappeared at my office for examination in September with every evidence of extension of the disease in that lung. General measures had failed to do more than to hold him *in statu quo* up to that time. I advised a trial of the serum. He discontinued everything in the line of treatment, such as hypophosphites, cod liver oil, etc., and took the serum, with the result that by Christmas all signs of active disease in the left lung had disappeared. Resonance had returned in a very gratifying manner, and there were left evidences of only a small cavity with some surrounding induration. His weight had improved beyond any previous weight he had ever attained, and he considered himself so well that in the middle of January he suddenly discontinued treatment, before I believed he was perfectly cured. The result is that two weeks ago, he had hemoptysis. I have not seen him since, and know not the source of the hemoptysis.

(To be continued.)

SELECTIONS.

Response to the Toast "The Babies."—Dr. I. N. Love of St. Louis, at a banquet given at St. Louis to the General Passenger Agents of the Southern and Western Railways, April 30, said: "We fathers too often desert the field and leave our wives alone to look after our babies, and this is wrong. The father is more closely related to the baby than he realizes, is indeed *particeps criminis*, in other words, equally responsible with the mother, but in the majority of instances we shirk our duty and throw the burden upon the shoulders of the one already weary in well doing.

There is no power that could make the mother waver in her performance of duty to her child. It is not always so with the father, but it should be. No more serious question confronts us than "the babies," and there is no question that should command a greater part of our best thought. We should remember that the baby is shot into this cold and cruel world without having been consulted either as to whether he wanted to come, what particular place he would like, what special kind of environment, or what individual equipment he would desire. Indeed, he is not consulted at all as to the coming, but oftentimes after arriving here he is consulted more than he should be as to his own proper management. The preceding proposition being true, surely the physical authors of the babies' being should appreciate the fearful responsibility they have assumed. They should determine to make it the business of their lives to develop their child in the right direction, physically, mentally and morally.

In the early part of the baby's existence he is largely a "vegetable"; he then becomes "animal," and later the "spiritual" begins to develop. The fullest opportunity should be furnished for the most complete vegetable and animal development possible, and to this end the rules of hygiene and health are of vital importance. The baby that is properly fed, and the mother usually takes care of this part of it, thrives, but the father should remember that during this period he himself should assume more than his usual share of the burdens. He should realize that the, to him, sweetest object on earth, the mother of his child, has a dual nature: that she has intellectual and fruit-bearing functions; that during the period when she is engaged as a fruit-bearer and doing her duty to her child, she should be relieved of the mental burdens that otherwise might fall to her, and receive more petting, fondling, coddling than usually falls to her lot. Fathers are too often so completely absorbed in money getting that they neglect to get acquainted with their babies. It has been said that it is a wise child that knows its own father, but I think indeed it is a wise father that knows his own baby and continues to know him from the time that he comes into the world until either the one or the other leaves it.

How few fathers cultivate the right kind of friendship between their children and themselves? Let us really make our babies feel and know that we are their best friend, next to their mother, on earth, and if we make them believe this we will have in our children our best friends. Let us treat our

baby friend the same as any other friend, respectfully, considerately, courteously, tenderly, generously, and when principles of right are involved, firmly, stubbornly even, and bend them in the right direction, and bend them early. Let us help the mother realize that all the coercion of a physical nature ever needed with a baby is before it is two years of age. The most important lesson a baby can learn is obedience. A puppy dog five days old can be taught to obey through physical punishment, and a baby need not be very old to be taught in the same way. Severity is never necessary, but a gentle firmness, a consistent stubbornness upon the part of the parent to secure absolute obedience as a regular habit of life, is essential.

We should teach our baby, first of all by example, to be just; to be kind; to be honest; to be sincere; to be polite; to be considerate of others; to be truthful. We should teach him, too, that reciprocity, the new golden rule, "Be good to all who are good to you," is essential to salvation in this life. We can early saturate the child with the full knowledge, a complete grasp of the meaning of the word reciprocity. Teach him that it isn't honest, that it isn't manly to accept favors from others selfishly and not reciprocate them to the fullest. With this thought in mind the child will feel and know that the kindness, the fostering care given him by his father, must be returned, and it will be returned with interest. The father who neglects his child is putting a mortgage upon the latter years of his own life and that of his child, and frequently foreclosure will come when least expected, and when he is least prepared to meet the burden involved.

Let us prize more highly the good opinion of our child and its mother than that of any other creature this side of heaven. Yes, gentlemen, let us feel that it is more dishonorable to neglect the coupons that have come to us from our matrimonial bonds than to neglect any business obligation on earth. I admire the man highly who has the courage to face the wide, wide world with the thought that he proposes to capture everything in sight within the limits of right, even though misunderstood, condemned, disliked, and yet who, when he faces his family, his babies, faces those who know that he is the dearest, best, most faithful, just and generous creature underneath the stars. Business pursuits and professional duties become seriously absorbing at times and prompts us to neglect the loved ones near us in a manner that we little dream of. We must determine, then, we big babies, to go hand in hand with our little ones all along the valley, up the hill and down the hill again, and as we make the journey, if we do our share we will be cheered and comforted when we approach the setting sun. Then here's to us all, babies as we are. Yes, we come into this world puling, puking infants, naked and bare; we go through the world puling, puking infants, each with his own share of sorrow, trouble and care. We go out of it puling, whimpering, helpless infants, faint, feeble, tottering, God in His infinite, omnipotent wisdom only know where, but all along the road if we are thoroughbreds here, we will be thoroughbreds there!

A Climacterium to Males.—In many males, there is manifestly a physiologico-critical period about the beginning of their fifth decade. This change of life is one primarily associated with nutrition. The digestive and assimilative functions begin to slow down between 40 and 50 years of age, and the organism as a whole, undergoes a readjustment. If the digestion remain active while assimilation becomes less perfect, an increase of weight, due to accumulation of fat, takes place. If, on the other hand, digestion is the first to fail, symptoms of dyspepsia, with associated loss of flesh, characterize the period of transition. It is in athletic individuals of active muscular habit that the manifestations are most marked. A time arrives when lessened nutrition renders it impossible to maintain the normal activity of the muscular system. The eliminatory organs perform their function less perfectly, and the processes of disassimilation are hindered. The accumulation of the products of metabolic tissue change in the system, reduces the vitality of the subject and indisposes him to the routine amount of exercise. If the subject fail to grasp the significance of these sensations he renders himself liable to various functional disturbances which may culminate in organic disease of the organ or organs most exposed to the strain. Even if he yield to the pressure put upon him, it takes some time for the muscular and vascular systems to tone down to the reduced standard of vitality, and during the period of adjustment he is apt to suffer from a variety of more or less distressing feelings; which not infrequently

determine mental depression. The change is not unlike that holiday spent in active physical exercise. There is the same want of harmony between nutrition and muscular exertion, but, in the waning adult, there is, of course, the factor of increasing arterial rigidity and general loss of tone on the part of the tissues. The so-called "critical period" is only critical in so far as the readjustment of the organism to changing conditions is interfered with. Those who have always led a sedentary life are less subject to these disturbances than the more robust and actively disposed. Once the harmony of the functions has been restored the individual resumes his normal existence, though on a lower scale, and he ceases to be liable to the visceral engorgements which are apt to resort from "retrogressive irregularity."—*Medical Press and Circular*.

PRACTICAL NOTES.

Chambellan's Rhino-pharyngeal Speculum can be managed with one hand, as the mirror is adjusted by a screw turned by the thumb without effort, leaving the other hand free.—*Bull. de l'Acad. de Méd.*, April 26.

Soothing Pomade For Congestive Alopecia With Cephalalgia.—(Leistikow.) Tinct. cantharides, 3 grams; chloral hydrate, 2 grams; lanolin, 5 grams; vaeelin, cherry-laurel water and lime water, àà 10 grams. For external use.—*Semaine Méd.*, May 4.

Physiologic Inferiority of the Tissues.—Tuffier considers movable kidney, dilatation of the stomach, enteroptosis, varicocele, etc., evidences of a congenital inferior vitality of the tissues, which requires medical and especially hygienic treatment, with surgery the last resort.—*Progrès Méd.*, April 30.

Ether Spray For Hypertrophied Spleen has proved extremely efficacious in relieving the respiration, the congestion of the organ and the pain, in twelve new observations of malarial hypertrophied spleen. The left half of the abdomen was sprayed twice a day with 25 to 30 grams ether, and in about a month the spleen was reduced to normal size.—*Semaine Méd.*, May 4.

Gastrorrhagia in Chlorotics cured by immobilization of the stomach is reported by Cipriani; three cases. After the failure of other measures the hematemesis was promptly arrested by a compressing bandage applied around the body over the stomach, combined with rectal alimentation, nothing allowed to pass the lips. The extreme thirst was met with injections of salt solution and the hunger by a subcutaneous injection of cocain which produced complete anorexia.—*Semaine Méd.*, April 27.

Artificial Serum in Epilepsy is advocated by M. de Fleury, who ascribes the etiology in many cases to auto-intoxication, which he combats with appropriate diet and lavage of the stomach and bowels, treating the circulatory apparatus by cardiac medication and artificial serum, possibly venesection. The injections of serum augment remarkably the effect of the bromid which he combines with them while increasing the diuresis, raising the arterial tension and maintaining the integrity of the intellectual functions, etc.—*Gaz. Méd. de Liège*, May 5.

Precision In Fluoroscopy.—A foreign body can be located much more accurately if the spot where it is apparently located is marked on the skin on the side toward the screen and also on the side toward the tube. Professor Angerer uses for this purpose a metal ring mounted on a handle, on pressing a button in the handle a colored pencil protrudes at the exact center of the ring and marks the spot. Changing the position of the tube and marking the spots again, shows the precise location of the foreign body. If the marks are closer together on one side than the other the body is nearer the surface on that side. Its position in regard to each surface can be found exactly by the formulæ: $A \div B$ (distance between the marks on one side) $\div A + B$ (distance between the marks on the other side), and $B \div A + B$.—*Chl. f. Chir.*, May 7.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JUNE 4, 1898.

THE DEADLY CAMP FEVER AND ITS PREVENTION.

During the past two months we have heard much of the danger to which our troops will be exposed from yellow fever in their expected invasion of Cuba, but nothing has been said of the future possibilities of a disease which during our Civil War affected every newly raised regiment soon after it went into camp. Typhoid fever was the camp fever of the Civil War. In the year 1861-62 it struck down 78.62 and killed 19.55 out of every thousand white men serving in the Army. It was a deadly disease under the conditions then existing in the field, for of every hundred cases 35.90 proved fatal among the white troops and no less than 55.69 among the colored men. It was not a disease of certain months or certain seasons, for, as shown by Dr. SMART in a diagram facing page 20 of the third part of the medical volume of the History of the War, the highest crests of its several waves of prevalence and fatality corresponded with a period about two months after each of the calls made by the President for the raising of new levies. Again the President of the United States is issuing his proclamations for troops; again new regiments are being formed and concentrated in camps of organization and instruction, and already from these camps comes the news-gatherer's information that everybody is well with the exception of one or two men who are in the hospital under treatment for typhoid fever. We know more about this fever now than we did then. We know that it is mainly propagated by the water supply; and in looking back we can see how it came about

that the camps of both the Union and Confederate Armies were ravaged by typhoid fever. A single regiment in an isolated camp may be able to preserve the purity of its water supply, but when twenty or thirty thousand men are camped in the same locality it is a difficult matter to prevent the drainage and filth of one regiment or brigade from contaminating the water-supplies of other parts of the command. Strict sanitary rules should be made and enforced concerning the use of the sinks that there may be no surface deposits to be washed by the next rainfall into streams used as drinking supplies. This is very well as a general sanitary measure against other diseases as well as against those that are water-borne; but there are special methods of preventing the spread of typhoid fever among the susceptible young men of the new regiments. There are special methods of purifying the water from this dangerous infection but each of the methods requires the expenditure of money for its installation and the exercise of much care to obtain satisfactory results. The Subsistence Department provides the soldier with hard-bread, bacon, coffee and many other articles constituting his field ration and each of these costs money; but the soldier's right to wholesome articles of diet has never been questioned. Should his right to be furnished daily with a ration of wholesome water be questioned? Water is more urgently required in the animal economy than food; its deprivation is expressed by symptoms of greater intensity and its frequent impurity is liable to cause disability and death. The troops in the field should be protected against this. The history of the volunteers called out by President MCKINLEY should show no such high crested waves of mortality from typhoid fever as that of the volunteers called out by President LINCOLN. Expense should not be considered when the well-being of the fighting men is concerned. It will be more than covered by the money hereafter saved in appropriations for pensions for disabled soldiers and dependent relatives. The soldier should be deemed entitled to a ration of water and the subsistence or some other department should be held responsible for its issue and its purity. We believe something of the kind will be done as an appreciation of the importance of pure water has of late been growing rapidly in the public mind. At our military posts, in the time of small economies "before the War," using this phrase in its application to current events, our medical officers were accustomed to recommend the boiling of their doubtful or suspicious water-supplies; but other methods of treatment giving pure and palatable results are available if the price be paid. Investigations have been completed, under the direction of the Surgeon-General in the laboratories of the Army Medical School, into the efficiency of certain suggested methods of purification which will, we hope, result in giving pure water to the troops and in lessening the death roll from typhoid fever.

THE CIGARETTE EVIL IN ITS MILITARY ASPECT.

A newspaper statement that in the medical examination of volunteers to meet the President's call to arms, a very large proportion, it is said as much as 90 per cent., of habitual cigarette users were rejected, has brought out considerable comment and some attempts at refutation of the charge against the popular indulgence. Even prior to the outbreak of hostilities, however, the question of the sanitary dangers of cigarettes was a living one, and it is not long since that an extended symposium, so to speak, upon the subject was published in one of the New York professional publications. In that the general consensus of opinion appeared to be that the maleficent effects of the habit have been very largely exaggerated before the public, and that the evil, if it be such to any extent, was not by any means deserving of all the condemnation it had received. If, however, the army examiners' experience is truly stated, it can not be denied that there is in it an element of national weakness that deserves the most thorough consideration. If 90 per cent. of cigarette smokers are unfit for military service according to the reasonably strict standard of army recruiting officers and examining surgeons, any extensive generalization of the habit is a matter to be most profoundly deplored.

There is before us another item bearing on this subject that emphasizes the danger, if such it be, of the use of cigarettes. It is said that the increasing mortality in the French army, which is stated to be steadily on the increase, is largely due to pulmonary affections that are themselves favored by the general habit of cigarette smoking. Other presumable causes are not more active than they were a few years ago, but this one evil seems to be constantly gaining ground and is therefore held as mainly responsible for the increased mortality from lung disorders in the French army.

Allowing full value to the possible inaccuracy of newspaper statements there is some occasion for serious thought in these items. Where there is so much smoke, to use an old saw, there must be some fire; the ever resilient popular belief in the dangers of cigarette smoking must have some foundation. It is certainly not altogether due to fanatical reformers to whom every form of stimulant or narcotic is an evil to be fought, for it has a much wider advocacy than can be found in that limited coterie. For a while it was maintained by some that the adulterations of the cigarette were the source of danger, but this has been practically given up as not supported by the facts—the average cigarette tobacco is no worse, if no better, than that indulged in in other ways. The peril seems to be in the facility the practice affords for unlimited indulgence, and perhaps it may be added, in the very common habit of cigarette smokers of inhaling the smoke, thus enlarging the area of absorption, facilitating the narcotization and very possibly also producing deleterious local action in the bronchi

and lung tissue that will, under favoring conditions, afford a more ready point of least resistance to the action of morbid germs. The very mildness of the grade of tobacco used is itself an aggravation of the danger, as has been pointed out by some of those who have discussed the subject, since it tempts to and makes more easy the pernicious practice of smoke inhalation. That this is a pernicious practice hardly requires argument, since it is plain enough that the larger the absorbent surface the more prompt and decided will be the narcotic action, and the combined effect of this with the more constant or frequent usage of tobacco that the cigarette habit favors, can not fail to be injurious to the nervous system whatever the grade of the tobacco or whatever individuals may say to the contrary. There is here a field for psychologic studies in our hospitals and laboratories and, from what has already been done in this direction, there is little doubt but that such researches will confirm the unfavorable opinion so commonly extant in regard to this habit of cigarette smoking as opposed to other forms of tobacco usage. The direct mechanical effect of smoke-inhalation in producing a pneumokoniosis or tabacosis is also worthy of consideration; it is possible that this has a direct weakening effect upon the lung tissue, reducing its power of resistance to germs and thus accounting for the alleged increase of mortality from pulmonary disorders in the French army.

Taking all the facts and all the possibilities together, it would appear that in the extension of the habit of cigarette smoking, with its consequent tendency to excess in tobacco narcotization, we have an element of danger to the community the greater because of its increase among the young and immature. The practice was originally a Spanish one, and it suggests a query whether the misfortunes of the Spanish nation may not be due in part to a race degeneracy thus produced. If so, it will be well for us and other nations to take warning from their example. In these days also, when wars are still in fashion, whatever can diminish the military strength of a people is a national calamity.

UNFIT FOR MILITARY SERVICE.

Since the closing days of the month of April the energies of a large number of medical men have been devoted to weeding out from the candidates for military glory, those who from any cause seemed likely to break down under the exigencies of an active campaign. The responsibility for much of the delay which has occurred in the mustering in of companies and regiments, has been placed upon these officers who have been charged with unnecessary strictness in excluding men for trifling defects. The Army requirements, as published in a recent recruiting circular, are that the limits of age should be eighteen and thirty-five years; the height for all arms of the service not less than 5 feet 4 inches, with a maximum limit of 5

feet 10 inches for the cavalry; the weight for infantry and artillery from 120 to 190 pounds, and for cavalry not to exceed 165 pounds. No minimum weight is prescribed for the last mentioned arm, but the chest measurement is required to be satisfactory. From 5 feet 4 to 5 feet 7 inches the measurement at expiration should be 32 to 33 inches, with 2 inches of mobility; from 5 feet 8 to 5 feet 11 inches, 33 to 34½ inches, with 2½ inches of mobility, and men of 6 feet and over, about 35 inches, with 3 inches of mobility. These are not unusual requirements. Moreover, examining boards were authorized to accept men otherwise eligible who did not conform exactly to the figures given in the circular. Nevertheless it appears that so many men, including some of local repute as athletes, have been rejected as unfit, that the daily papers have taken note of the subject and assumed that the proportion of rejections was as unusual as it was unexpected. They endeavor to explain it by suggesting a decadence in the physique of American youths, owing to the prevalence of the cigarette habit, or by holding the bicycle responsible for heart strain, and its low handle bar for round shoulders and deficient chest measurement. But the percentage of rejections, when officially published, will probably be found to be much smaller than the newspaper articles would lead us to expect. For several years past about 15,000 candidates for enlistment have been examined annually in keeping our small Army up to its peace strength of 25,000 men, and nearly one-half of these candidates have been rejected as unfit for military service. It is hardly to be supposed that men obviously unfit would have presented themselves for examination, yet one-half of those who evidently considered themselves able to do military duty were not so considered by the medical and recruiting officers. In time of war we should expect the percentage of rejections to be increased because in view of the privations, exposures and fatigues incidental to field service in actual war, the minimum of physical qualifications should be raised rather than lowered, chiefly because the lowering of the age limit from twenty-one to eighteen years permits many to come up for rejection on account of defective physique, whose age in time of peace would have barred them from consideration. We are confident however, no matter what the percentage may be, that the medical men engaged in this important work have done their duty faithfully and well in the interests of present efficiency and the protection of the pension rolls of the future, from cases of disability really due to causes existing prior to enlistment.

THE SYNOVIAL MEMBRANES.

A recent article concerning researches in the etiology of articular rheumatism, recalls those lately carried on by Vienna investigators. Their work was directed not only toward discovery of the causative

factor of rheumatism, but to determine why the joint forms a *locus minoris resistentiæ*.

The histologic studies of HOFBAUER led him to the conclusion that the low resisting power was due to the structure of the synovial membrane. Not only is it very vascular in all its layers, but its vessels passing close to the joint surface, from which they are separated by a thin layer of tissue, bend on themselves and pursue a tortuous course directly under, and parallel to, the surface of the joint. Some authors assert that the capillaries extend free into the joint cavity, covered only by synovial cells. He failed to confirm the findings of BUDAY, viz., that the endothelial cells lining the capillaries protrude into the lumen; that the more swollen these cells and the less firm their union, the more uneven the inner wall of the capillary, thus forming little depressions between the cells which render especially favorable the lodgment of floating bacteria. BUDAY believed that joint metastasis occurs only by embolism, with suppuration, necrosis and breaking down into the joint.

HOFBAUER holds the opinion, based on his histologic investigations, that the rich vascularity of the synovial membrane and the arrangement of the capillaries account for the frequency of joint lesions in blood infections and intoxications. In the former the lesion is due to embolism, or the direct passage from capillaries into the joint. That this is possible, he (as have also others) has been able to verify by experiments on animals. The arthritis of gout, as well as the joint swellings sometimes following the use of antitoxin, illustrates the affections of blood intoxications.

The histologic researches of HOFBAUER have been especially supportive to the bacteriologic investigations of CHVOSTEK. The latter has resorted to similar experiments on animals to determine the permeability of the synovial membrane, and he found microbes in the joint sixteen hours after injection of the animal with the same. On the other hand, his bacteriologic examinations of joint effusions, and microscopic examinations of synovial membranes, have proved negative, as has also the blood of rheumatic patients. His negative results are confirmed by other authors, some of whom even state that a positive finding speaks against rheumatism. CHVOSTEK, therefore, assumes that, in view of the easy permeability of the synovial membrane and the failure of finding any microbes in the effusion, membrane or blood of rheumatic patients, the joint changes are due to toxic substances which would pass as easily as would the microbes. He does not deny that the toxins are produced by germs, but asserts that they are not demonstrable in joints or blood.

SINGER believes rheumatism to be a variety of pyemia, citing a series of cases with examinations of joint contents with positive bacteriologic results, as well as positive findings of blood in 15 per cent. of the

cases. He lays especial stress upon the erythema multiforme occurring in rheumatism, comparing it with the eruption of pyemia, in which he has found staphylo- and streptococci. He regards the erythema as a skin localization of circulating microbes (the cases of purely nervous form being excepted), and maintained that the researches of HOFBAUER are equally supportive of his findings as of those of CHVOSTEK, claiming that the presence of microbes in joints is not necessarily demonstrable, as they may be few in number, or remain as sediment in the joint.

It is evident that the methods of one or the other of these investigators have been defective, as their findings stand in striking contrast, and such decided differences in results could hardly be referred to defective diagnosis by SINGER. Both concur in the opinion that the blood acts as the transmitting medium for the cause of the local change. With this premise one would expect the blood would give positive results at some stage of the disease. This many others beside CHVOSTEK have failed to find, while in 40 per cent. of the cases of pyemia where the blood has been examined by various investigators, microbes have been found.

No less interesting than the discovery of the indisputable cause, would be the establishment of the identity of the same in the various clinical manifestations now attributed to this undetermined factor of rheumatism. The endocarditis, the chorea, the pleuritis and the pericarditis that may occur singly or collectively, co-incidentally, preceding or following an articular rheumatism, are daily experiences of clinicians.

The following case may serve as a sample of some of the various complications:

A boy 10 years of age was admitted to the hospital in June of last year. His history in brief was as follows: About six weeks before he was seized with pains in several joints, which became swollen and very sensitive on pressure or motion. A physician called at the time made the diagnosis of rheumatism. Under treatment acute symptoms subsided and the boy was around and playing after a few weeks. About this time his parents observed jerking movements of arms and legs, which gradually became more aggravated until entrance into the hospital.

Physical examination.—Child of average size for his age; nutrition fair; slight rachitic changes in skull and legs; all joints are freely movable, painless and free from effusion; articulation normal; choreic movements of arms and legs; lungs negative; heart on palpation shows apex in the fourth intercostal space and the width of one and one half fingers outside of the mammillary line; no tremor. Percussion: Upper border of dulness corresponds to lower border of third rib; left coincided with apex; right less clear note over lower part of sternum than upper but absolute dulness on left sternal border. Auscultation: Loud systolic murmur over apex, decreased in intensity toward base; second pulmonary tone accentuated. A few days later a presystolic murmur was also heard over apex. After an interval of several days auscultation gave a similar result to that found on entrance; liver and spleen dulness normal. Examination of sensibility showed right hemi-hyperesthesia, which afterward disappeared. Temperature varied

from one to two degrees above normal; pulse 80 to 90, with no qualitative changes.

Diagnosis.—Acute endocarditis with mitral insufficiency, chorea; hemi-hyperesthesia regarded as hysterical. The diagnosis of endocarditis was based on the changeableness of the auscultation signs, no weight being attributed to the percussion findings because of patient being a child with high-standing diaphragm, placing apex in fourth interspace. From this circumstance it would normally lie outside of the mammillary line, though the case in point slightly exceeded the limit of this. After the patient's entrance into the hospital the choreic movements subsided, but did not disappear. Three to four weeks later they became more marked and the patient complained of pain in the right side and later of pain under the lower part of the sternum. Examination of chest showed on right side, posteriorly, absolute dulness eight fingers' breadth above the previously determined lung border; left side unchanged; heart dulness the same, with the addition of pericardial friction-rub, heard loudest along the sternum and over the base. Later examinations showed the characteristic increase in the heart's dulness accompanying a pericardial effusion. This was not to be clearly defined on right border because of its merging into dulness of pleuritic effusion. Aspiration gave a serous fluid. Present diagnosis, chorea, mitral insufficiency, pleuritis with effusion, pericarditis.

Traced from the first illness, that of articular rheumatism, we have successively developing endocarditis and chorea. The order in which these occurred must remain a matter of conjecture. Clinical experience shows that these three affections may alternate in any order, which circumstance would tend to confirm the identity of their etiology. The later development of inflammation of the pleura and pericardium showed these serous surfaces to have more resistance than the more susceptible synovial membrane.

It seems reasonable to assume that the etiologic factor had not been eliminated, nor had it ceased in its activity, as the clinical symptoms at no time entirely subsided.

A ROYAL ARMY MEDICAL CORPS.

For many years past the grievances of the medical officers in the British service have been of such a character as to enlist the sympathies of the medical profession. All the great medical schools have been in the habit of discouraging their students from entering into the open competition for service in the the Army Medical Staff. The standard of efficiency has thus been lowered, while more than 10 per cent. of the authorized positions have remained unfilled. As the Army, in consequence, has not enough of medical officers to meet the ordinary requirements of peace, the question of what would happen in the event of a serious war has been a subject of anxiety both to the medical profession and the War Office Authorities. A committee of the British Medical Association some time ago formulated the grievances of the medical staff and the demands of the profession. The medical officers of the army complained that while they had no longer that connection with individual regiments, which formerly gave them a recognized status and a social intimacy with their

combattant colleagues, they have been compensated by no substantive military rank, the relative rank given them with the cumbersome titles of surgeon-colonel, etc., having proved to be inadequate to raise their status above the level of a civilian serving with the army. The English papers of May 5, 1898, indicate that these unsatisfactory conditions will soon be remedied. At a banquet given at the Mansion House by the Lord Mayor to Sir SAMUEL WILKES, President of the Royal College of Physicians, Sir WILLIAM MACCORMAC, President of the Royal College of Surgeons, and the leading members of the medical profession, the Secretary for War, Lord LANSDOWNE, made a speech in which he frankly declared that the War Office had determined to treat the Army Medical Staff liberally and to remove the grounds for the complaints that had so long been ineffectually urged. He stated that the medical officers of the army will hereafter bear the military stamp. They will have the same titles, up to the rank of colonel, as other officers of the Army and will exercise command of their own corps, the Royal Army Medical Corps. It may therefore be confidently assumed, according to the *Times*, that at the next public competition there will be a marked improvement both in the number and quality of the candidates for the Army Medical Service.

The United States Army Medical Department has at the present time a difficult work before it in organizing and equipping its medical service and hospital corps, but fortunately it is not handicapped by any of the conditions which are now for the first time undergoing radical treatment in the British service. It makes its start in this war with Spain in full possession of that which has been the objective of the British medical staff for years, rank in the army and command over its own hospital corps men.

THAT ADVERTISING CIRCULAR.

We reproduce the following from *Printer's Ink* of May 25, which is self-explanatory. With this we close the subject.

TO RIGHT A WRONG.

"THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,"
Published Weekly under Direction of
Board of Trustees.
61 Market Street.
CHICAGO, May 16, 1898.

Geo. P. Rowell Advertising Co:

Replying to your letter of May 14, I have to say that on examination of the blank sent to this office concerning the alleged agreement to publish the Ripan's Chemical Co.'s prepared medicine, I find that the blank was never in this office to the knowledge of any responsible person connected with it. The handwriting in the blank is not that of any person connected with this office. The typewriting does not conform to that used on the machines in this office. Furthermore, the blank is not signed. The alleged rate shows that it is put in as a monthly rate instead of a weekly rate, which does not conform to the business of this office. In addition I will say that we had rejected this advertisement because of the ruling of the trustees, and we could not have accepted it under any circumstances. As the publication of the name of this journal in a

list of those accepting the advertisement, without authority, has been a pecuniary loss to the JOURNAL I trust that you will publish this letter in order that the wrong may be righted. I am, gentlemen, faithfully yours,
JOHN B. HAMILTON.

THE JOURNAL SPECIAL TRAIN TO DENVER.

The JOURNAL SPECIAL TRAIN will leave the Union Depot, Adams and Canal Streets, Chicago, Saturday, June 4, at 11 P.M., via the Chicago, Burlington & Quincy Railroad, arriving in Denver Monday morning 7 A.M., in time for the meeting of the American Academy of Medicine, the American Medical Editors' Association and other medical organizations holding sessions on Monday.

Pay no attention to statements other than those announced in the JOURNAL. The reason for arranging for the stop-over on the return trip was owing to the fact that the Exposition at Omaha will be in much better condition then than now. Passengers from the East taking the JOURNAL SPECIAL at Chicago may have their stop-over arranged without extra cost.

The "Special" will run through. Tickets will be good for thirty days. The rate will be one fare and \$2 for the round trip, the most favorable rate yet granted the ASSOCIATION.

There is but one JOURNAL SPECIAL train, and that is managed solely in the ASSOCIATION interests. Personal and not ASSOCIATION interests have promoted most of the other "specials." Stand by the regular JOURNAL train, Chicago to Denver via the *Burlington* route.

CORRESPONDENCE.

Second Attacks of Measles.

ALMA, MICH., May 17, 1898.

To the Editor:—Some weeks ago, I saw in the JOURNAL a communication from some one setting forth, tentatively, the theory that a second-time case of measles will not communicate measles. Six weeks ago Effie G. was taken sick with measles the second time. In the same family is a child of four years who never had measles. She remained in the room with the sick girl nearly all the time, and did not take the disease. If this is the principle in these cases it should be known.

Yours,

I. N. BRAINARD, M.D.

ASSOCIATION NEWS.

Executive or Business Committee.—The first meeting of the Executive Committee of the AMERICAN MEDICAL ASSOCIATION will be held in the club room of the Brown Palace Hotel, Denver, Colo., Monday afternoon, June 6, at 5 o'clock. Subsequent meetings of the Committee will be held at the same time and place each afternoon during the meeting of the ASSOCIATION, unless otherwise ordered by the Committee. It is essential for the successful conduct of the ASSOCIATION that all the members attend the meetings of the Committee. L. DUNCAN BULKLEY, M.D., Secretary.

Announcement.—The following arrangements have been made for the Denver meeting of the AMERICAN MEDICAL ASSOCIATION:

Section Dinners will be given June 7, at 7:30 P.M., and social entertainments will be given on other evenings during the week.

Ladies' headquarters will be at Unity Church, where they will be received by the wives of physicians of Denver. Arrangements have been effected for their entertainment during their visit, and committees will escort the visiting ladies to the various points of interest in Denver.

On Friday June 10, a complimentary excursion to Idaho Springs and around the loop will be given by the Colorado State Medical Society. At Idaho Springs, the ASSOCIATION will be entertained by the citizens.

On Saturday, a complimentary trip will be made to Colorado Springs under the auspices of the Committee of Arrangements. At Colorado Springs the ASSOCIATION will be entertained by the local physicians and citizens. Visits will be made to all points of interest in the vicinity. Arrangements will be made for trips to Pike's Peak and the celebrated mining camp of Cripple Creek at low rates of fare.

At a date to be determined, special trains for Glenwood Springs will leave Colorado Springs via The Denver and Rio Grande Railroad and the Colorado Midland Railroad. Tickets \$5.00, good going via one railroad and returning the other, and for ten days from date of issue.

The trip to Glenwood is one of the most attractive in Colorado, giving excursionists a view of some of the finest scenery in the Rocky Mountains, including Pike's Peak, Ute Pass, the Valley of the Arkansas, Hagerman Pass, Canons of the Roaring Fork and Frying Pan, Canons of the Grand and Eagle Rivers, Tennessee Pass and the Royal Gorge of the Arkansas and passing through the cities of Pueblo, Leadville, Canon City and Florence.

Special Hotel rates will be given by the Hotel Colorado and other Hotels of Glenwood Springs. The springs, baths and swimming pool will be free to the ASSOCIATION.

Special cars will be hauled on the Colorado Springs train and the Glenwood Springs Special, only when handed to the railroads with their full capacity.

Railroad Rates.—The Western Passenger Association, Chicago, formally announces the following rates for the Denver Meeting of THE AMERICAN MEDICAL ASSOCIATION, June 7-10, 1898:

Rate.—One regular first class normal tariff (not temporarily) fare, plus \$2.00, for the round trip from Association territory to Denver, Colorado Springs and Pueblo, Colo., and return.

Dates of Sale. Tickets to be sold from Eastern Committee territory, June 2, 4 and 5, and from Trans-Missouri territory, June 5 and 6, 1898.

Limits.—On going trip tickets to be good for continuous passage commencing on date of sale up to first Colorado common point en route: stop-over to be allowed on going trip at intermediate Colorado common points, but to arrive at destination not later than June 7, 1898. The return to be continuous passage beginning on date of execution by joint agent, with the provision that the return passage shall not commence earlier than June 12, nor later than July 6, 1898. Tickets may be executed for return at destination or either of the other Colorado common points en route. Purchaser to commence his continuous return journey from point of execution.

Diverse Routes.—For this occasion tickets may read west of the Missouri River, going one route and returning another via any regularly authorized route via which regular short line one way rates are properly applicable.

SOCIETY NEWS.

Meeting of the Medical Publishers. The fifth annual meeting of the American Medical Publishers' Association will be held in the parlor of the Albany Hotel, Seventeenth and Stout Streets, Denver, Colo., June 6, at 2 o'clock p.m. The following program has been arranged: 1. Meeting of the executive committee. 2. Reading minutes of previous meeting. 3. Reading correspondence from absent members. 4. President's address. 5. Reports: *a*, executive committee; *b*, arrangement

committee; *c*, committee on resolutions; *d*, committee on publication; *e*, treasurer; *f*, secretary. 6. Applications for membership. 7. Presentation of papers: "The Dignity of Advertising," by H. C. Smith, New Orleans; "Some Unique Features," by Henry Waldo Coe, Portland; "The Shadowy Ethics of Journalism," by T. O. Summers, St. Louis; "The Local Journal," by A. R. Axtell, Denver; "The Problems in Medical Journalism of today," by H. D. Reynolds, New York City; A paper by J. R. Clausen, Philadelphia; volunteer papers and subjects for discussion. 8. Resolutions introducing new business. 9. Miscellaneous business. 10. Election of officers. Adjournment. It is expected that at this meeting the question of admitting nostrum and lay press advertisers to the columns of the medical press will be thoroughly ventilated and discussed. Some of the objects of this association are to protect against mutual enemies and impostors; and encourage a friendly feeling between publishers and editors; to teach and to be taught; to solve the problems which are continually confronting those engaged in medical journalism; to make the medical press of the country more worthy of a place in literature, and to make more uniform and consistent the business end of medical journalism. Editors, publishers and others are cordially invited to attend. William Warren Potter, M.D., President; Charles Wood Fassett, Secretary.

The Fifth District Branch of the New York State Medical Association held its fourteenth annual meeting in Brooklyn, N. Y., May 24. The President, Dr. N. W. Leighton, delivered an address on "The Physician and his Profession," which was ordered published. Sketches of deceased members by Drs. R. M. Wyckoff and John Shradly were also read. During the afternoon session there was a written discussion on the phases and treatment of gonorrhea, in which Drs. Robert W. Taylor, J. W. S. Gouley, William E. Beardsley, Lawrence Coffin, William McCollom, J. C. Bierwith, L. Grant Baldwin, George H. Mallett, Walter B. Chase, Fred. H. Wiggin, Robert Newman, N. L. North, Jr., A. Matthewson, L. A. W. Alleman and Thomas H. Mauley were participants.

West Virginia State Medical Society.—The annual session of this Society was held in Martinsburg, May 18-20. Dr. J. N. Alley of Benwood presented a paper on "Cancer of the Tongue," Dr. R. W. Haglett of Wheeling one on "Sexual Perversion," and Mr. Munchen of Cincinnati an address on "Hypnotism," the first day, morning session. At the afternoon session Dr. Clyde S. Ford of Wheeling read a paper on "Fracture of the Patella," speaking of the "Treatment by Mediate Ligation" with a report of fifty cases. A paper on "Exophthalmic Goiter," by Dr. L. D. Wilson of Wheeling was then heard. The members of the association then discussed these papers. On succeeding days Dr. C. S. Hoffman of Keyser read the report of the Committee on New Remedies, and papers were read by Drs. S. L. Jepson, Clyde S. Ford and L. D. Wilson of Wheeling.

Washington State Medical Society. The ninth annual meeting of the Washington State Medical Society was held in Seattle, May 10 and 11, and was in many ways the best meeting since the organization of the Society, especially in the character of the papers read and the interest taken in the discussions: The United States Marine-Hospital Service was officially represented by Passed Assistant Surgeon S. D. Brooks. The Oregon State Medical Society was represented by Wm. Jones, president, A. C. Smith and K. A. J. McKenzie, both ex-presidents, and Henry W. Coe, editor of *Medical Sentinel*. The officers elected for the coming year were: President, Henry W. Dewey of Tacoma; vice-president, J. W. Hickman, Tacoma; secretary, Chas. McCutcheon, Tacoma; treasurer, J. W. Bean, Ellensburg. The next meeting will be held in Tacoma on the second Tuesday in May, 1899. The Society took the preliminary steps toward the organization of a State medical library, and a board

of trustees was appointed to carry it forward. It will be operated in connection with the Seattle city library. This is the first public medical library to be organized in the Northwest and, so far as we know, the only one west of Denver.

PUBLIC HEALTH.

Yellow Fever in West Indies.—Dr. Anderson of Georgetown, British Guiana, has published a pamphlet narrating the results of an experience of thirty-four years in the American tropics. He was fortunate in having had a certain amount of preliminary drill as to yellow fever from able and experienced men before he had to treat his first cases, and he refers to the difficulties with which the inexperienced practitioner has to contend who is called upon to treat disease without any previous clinical knowledge of it. The author's remarks in this respect are not only applicable to yellow fever but to diseases of tropic and subtropic climates generally. The book contains but little on the pathology and bacteriology of yellow fever; it consists mainly of reminiscences of a clinical and therapeutic nature and of impressions derived from the author's practical acquaintance with that disease. In the first chapter the health conditions of the West Indies formerly and at the present time are briefly described and they furnish a striking testimony to the prophylactic results of progressive medical and sanitary work. The change is a very remarkable one, for formerly, owing to a disregard of obvious insanitary conditions and considerations of personal hygiene and defective medical knowledge, the mortality among British troops and Europeans generally was enormous, whereas under improved sanitation, improved habits of life, a clearer appreciation of the predisposing causes of disease, and better methods of treatment the death-rate has been steadily diminishing, until the West Indies may now be reckoned as among the most healthy of the British colonies, whither, as we know, tourists and persons in delicate health often nowadays proceed as a winter resort. Practically speaking, we may say that about the best thing to do in the event of an outbreak of yellow fever on shipboard is to put to sea at once and run toward the north. The author deals with the geographical distribution of the disease and its causes, reference being made incidentally to the bacteriologic observations of several writers, and to those of Sanarelli of Montevideo and Havelburg of Rio Janeiro in particular, regarding the existence of a specific organism as the essential cause of yellow fever. The susceptibility to attack is dealt with and it is pointed out that while natives and negroes have a relatively small susceptibility to yellow fever they are nevertheless occasionally attacked by it. The symptoms and course of the disease and the state of the urine in yellow fever are discussed; the observations regarding the latter point are valuable.

Legislation in Ohio Regarding Quack Medicines.—The *Cleveland Medical Journal* is righteously indignant over the opposition that has been, through mercenary means, raised against the "Bennett bill." This bill merely provides that "patent medicines" shall have their formula printed on their labels. There is nothing unreasonable about this, but the *Leader* sees fit to antagonize the bill as being "An Attack upon Business Men," just as if nostrum-makers were genuine merchants. So far as we can see, there is nothing in common between real business and the patent medicine business. The sawdust and gold brick business are more intimately related with the patent medicine "business." But to return to the *Journal*, which says, "It is impossible to lay aside the suspicion that the pressure which the patent medicine makers are known to be making on all the newspapers is the reason of the *Leader's* attitude. What other reason can there be? Its arguments are of a most surprising character. Absolutely the sole argument advanced against the proposed measure is that few pat-

ent medicines contain enough poison to be deleterious to health, and that 'nearly every physician's prescription contains one or more poisonous ingredients, and the compounds made from these prescriptions would be as deleterious to health as any patent medicine if taken in doses larger than are indicated by the directions.' Passing by the obvious fact that the last sentence entirely begs the question and destroys the argument, and also the fact of its general misrepresentation, one can but wonder if the writer of the above was simply fatuous or deliberately intended to deceive when he neglected to state that the physician's prescription is always on file at the drug store where it was filled, and hence the composition of the medicine made up therefrom is always readily ascertainable; when he further neglected to allow anything for the special training of the physician, taken for the purpose of learning how to use medicine intelligently, and further neglected to allow for the care of the physician under which the effect of the remedy is watched and the precautions taken to avoid ill consequences of over-use. If the opponents of the Bennett bill have only this style of 'argument' to urge against its passage, even the Ohio Legislature would be promptly compelled to put the law upon the statute books. Unfortunately a much more potent, persuading and insinuating 'argument' is at hand for use on both the newspapers of the State and the lawmakers themselves."

Vaccination and Smallpox.—The Council of the British Medical Association have published a tract and a leaflet; the latter being an abstract of the former, in answer to the anti-vaccination propaganda that is ever and again cropping out in England. The *British Medical Journal* for March 5, 1898, publishes both documents in full. Following is the text of the leaflet: "1. The mortality of smallpox is much less now than in pre-vaccination times. 2. The greatest diminution in the smallpox mortality is found in the early years of life, in which there is most vaccination. 3. In countries where there is much vaccination and re-vaccination relatively to the population, there is little smallpox. 4. In classes among which there is much vaccination and re-vaccination there is little smallpox. 5. In places where smallpox prevails it attacks a much greater proportion of the unvaccinated than of the vaccinated; especially where the vaccinations are comparatively recent. 6. In houses invaded by smallpox in the course of an outbreak not nearly so many of the vaccinated inmates are attacked as of the unvaccinated, in proportion to their numbers. 7. The fatality rate among persons attacked by smallpox is much greater, age for age, among the unvaccinated than among the vaccinated. 8. It can not be truthfully alleged that independently of vaccination, smallpox is a milder disease now than in former centuries. 9. The degree of protection conferred by vaccination corresponds to the thoroughness with which the operation has been performed, three or four marks being much better than two or one, and a large mark much better than a small one. 10. Sanitation can not account for the facts above set forth. 11. Thorough isolation of smallpox cases in hospitals is a useful auxiliary to vaccination; it is no substitute for it. 12. Vaccination is very safe. 13. Calf lymph is now available to boards of guardians, etc., for the vaccination of every child in this country" (England). These twelve statements are taken up seriatim in the tract and proved by statistics, etc.; the whole seems to be a very clear and succinct statement of the incontrovertible evidence for vaccination.

How Contagious Diseases are Disseminated.—To those who wonder how cases of contagious disease spread through a community, the following account, taken from the local paper of a town in western Massachusetts, may not prove uninteresting. On February 3, a young man who found occasional employment as a railroad news agent, was taken sick in the hotel where he lived. A physician was called, who reported that the disease was smallpox, and told him to keep the door of his room locked

and admit no one except a friend, a freight brakeman, who remained with him and took care of him. The manager of the hotel was present, knew what the diagnosis was, and is supposed to have understood the importance of isolation. Notwithstanding this, as the boy said, "everybody in the house dropped in to see me." Many of his newsboy chums called, and some of them spent a good deal of time with him, sitting socially on the bed. He was also visited by several young women acquaintances, who were employes in a shoe shop and who returned to their work. The newsboys returned also to their vocation. Two days after the physician who was first called saw the case, another physician was called, the diagnosis of smallpox was made and the Board of Health notified. Twenty-four hours later action was taken and a house on the outskirts of the town was secured for a pest-house, but no one in the town could be persuaded to furnish conveyance. Finally, a man living in a neighboring town, for the consideration of ten dollars, furnished a wagon, and the doctor and the brakeman who acted as nurse made the transfer. In the language of the reporter: "The equipage had the street all to itself. People were afraid to even look at it. One young woman in town who chanced to see it has since been in a miserable state of unstrung nerves, and is thoroughly convinced that she 'caught it.'" The brakeman has been quarantined in a room on the top floor of the hotel, and the hotel has been disinfected with sulphur and other disinfectants. Aside from this no quarantine has been established, and the hotel has continued doing business as if nothing had happened. The barber shop, bathing establishment and saloon connected with the hotel continue to do a thriving business. Many people, however, avoid the street in which the hotel stands, and small boys having occasion to pass the building have been observed to hold their noses and run past at full speed. All who were known to have been exposed have been vaccinated, and vaccination is being generally performed throughout the town. —*Boston Medical and Surgical Journal*.

NECROLOGY.

JOSEPH STEDMAN, M.D., Boston, died at Watkin's Glen, N. Y., May 17, aged 63 years. At the breaking out of the Civil War he enlisted for three months in the Sixth Massachusetts. When his time expired he re-enlisted, and returned to Medfield and raised a company, of which he was made captain. This company was in the Forty-second Massachusetts. During the war he was promoted to lieutenant-colonel, and after the capture of Colonel Burrill he was acting colonel.

LOTT SOUTHARD, M.D., Geneva, N. Y., 1852, died at his home in Newark, N. J., May 14, from diabetes. He was born in Basking Ridge, N. J. seventy-one years ago, was long identified with St. Barnabas Hospital as one of its surgeons, and at the time of his death was also a member of the Newark Board of Trade.

FREDERICK L. DIBBLE, M.D., New Haven, Conn., May 15, aged 68 years.—Thomas B. Dorsett, M.D., Manchester, Va., May 19, aged 62 years.—C. Earley, M.D., Ridgway, Pa., May 16, aged 74 years.—J. D. Kincaid, M.D., Catlettsburg, Ky., aged 89 years.—Jonathan Kneeland, M.D., South Onondaga, N. Y., May 21, aged 86 years.—Alexander Barton McWilliams, M.D., Washington, D. C., May 17.—Andrew Manning, M.D., Plainfield, N. J., May 19, aged 37 years.—A. P. Ormsby, M.D., Kansas City, Mo., May 18.—Charles A. Shure, M.D., Port Deposit, Md., May 14, aged 57 years.—George W. Freeman, M.D., University of Pennsylvania, 1862, of Freemansburg, Pa., died May 16 of paralysis.

DEATHS ABROAD.—Dr. Anton Krassowski, the leading gynecologist of Russia, for many years professor of midwifery in the Military Medical Academy of St. Petersburg, author of an *Atlas zur Ovariologie*, lecturer on midwifery and diseases of women, etc., aged 77 years.—Dr. Ludwig Schillbach, extraordinary professor of ophthalmic surgery in the University of Jena, aged 73 years.—Dr. George Rosenbaum of Berlin, a neurologist, aged 40 years.

MISCELLANY.

High Degrees of Myopia, according to Knapp of New York, are more frequently seen in Europe than in America.

The Burning of the Hospital at St. Hyacinthe, near Quebec, May 16, has resulted in fourteen deaths, and this number was expected to increase. At date of writing three missing are supposed yet to be in the ruins.

Revised Mortality Statistics as applied to the population of the globe as a whole are stated by an exchange. Only 900 persons out of 1,000,000 die from old age, while 1200 succumb to gout, 18,400 to measles, 2700 to apoplexy, 7000 to erysipelas, 7500 to consumption, 48,000 to scarlet fever, 25,000 to whooping cough, 30,000 to typhoid and typhus, and 7000 to rheumatism. These averages might be considerably varied by careful autopsies, but perhaps fairly approach conclusiveness when the wide columns of figures are taken into account.

A New Vegetable Hypnotic, *Casimiroa Edulis*.—The study of the flora of Mexico, undertaken by the National Medical Institute, has already resulted in a new hypnotic, analgesic and anti-thermic, extracted from the seeds of the *casimiroa edulis*, a *zanthoxylum* of the rue family. Long experimentation and tests on several hundred persons have established its action, its freedom from secondary effects and determined the toxic dose. It does not seem to produce sleep, but rather to favor natural sleep, from which one wakes refreshed in four to six hours. It is especially adapted to insomnia from cerebral excitement or alcoholism. The northern cousin of the shrub, prickly ash, has long been known as the "toothache tree."

Titles.—The *New York Tribune*, in a humorous comment upon the question raised at the State convention at Little Rock, Ark., regarding the right of those other than teachers in colleges and universities to the title of "Professor," which was decided in the negative, pronounces the custom "an old voluntary system—not seriously taken even in America." We are consoled in the present instance by the omission of reference to our own calling, which is so wantonly accused of follies not quite grown into sine such as these. England, France and Germany have their share of allusions and apologies, but the insignificant "medical man" is not noticed, unless by a mere reference to our Anglo-Saxon brother who prefers "Esq." after his name rather than "Prof." before it. "On the whole," concludes the article, "we are lucky to be free of many of the questions about titles which complicate life in Europe so much. Certainly we are not as yet oppressed by them."

Recognition of the American National Red Cross.—It is understood that the President has directed the recognition, for any appropriate co-operative purposes of the American National Red Cross, Miss Clara Barton, president, as the civil central American Committee in correspondence with the International Committee for the relief of the wounded in war. So far as international correspondence with the Swiss Government in relation to the deliberations of the Geneva conferences is concerned, this government has uniformly recognized the American National Red Cross as the only civil body in the United States, which is regularly affiliated with the International Committee of Berne, for the purpose of carrying out the arrangements elaborated by the various conferences held at Geneva; and the representatives of the American National Red Cross at those conferences have uniformly attended with the sanction of the United State's Government. The army orders which we published in the last issue of the *JOURNAL* show that the military authorities have made all arrangements for the delivery of the neutralizing Red Cross brassard of the Geneva Convention, to those authorized to aid the medical department in its service in the field.

Records of Sick and Wounded in time of War.—The Act of Congress approved April 22, 1898, authorizing the organization of the volunteer army, requires all regimental and other medical officers serving with volunteer troops in the field or elsewhere, to keep a daily record of all soldiers reported sick or wounded as shown by the morning calls or reports, which records at the disbandment of the organizations will be filed in the record and pension division of the war department. To permit of this ultimate disposition of the medical records of the volunteers without interfering with the medical histories of men belonging to the regular army medical officers, who may have under their care patients belonging to both organizations will have to keep a separate set of records for each organization. The Surgeon General of the army has therefore called upon the surgeons in charge of general hospitals to have separate registers of patients, and monthly reports of sick and wounded made for regular and for volunteer troops. Similar instructions have been issued to surgeons in charge of hospitals in the field in which regulars and volunteers are likely to be treated side by side. In time of peace monthly reports of sick and wounded are required to be forwarded in duplicate, one copy to the chief surgeon and the other direct to the Surgeon-General, but during the war only one copy is called for, to be forwarded from general hospitals direct to the Surgeon-General, and from field hospitals to the Surgeon-General through chief surgeons.

Field Supply Table of the Medical Department U. S. A.—The Surgeon-General has issued a Field Supply Table, approved by the Secretary of War, May 9, 1898, to meet existing army conditions. It provides for the use of regimental surgeons, two medicine chests, marked No. 1 and No. 2, containing a varied selection of drugs, many in the form of compressed tablets, instruments, dressings and books of reference such as Nott and Firth's "Hygiene," Osler's "Practice of Medicine," Zuckerkandl's "Operative Surgery," Stephenson's "Wounds in War" and Hare's "Therapeutics." Each private of the hospital corps is provided with a pouch containing aromatic spirit of ammonia, first-aid packets with pins, scissors, jack knife, wire gauze for splints, bandages and plaster, while each man on duty as orderly to a medical officer carries some additional articles such as a pocket case, rubber bandage, ligatures, chloroform and a hypodermic syringe. The medical officer is provided with a field case, field desk, lanterns, litters, etc. The field desk is furnished with stationery, blank forms and copies of the army regulations, manual for the medical department, drill regulations and Smart's "Handbook for the Hospital Corps." It is stated that renewals of supplies can be obtained by regimental surgeons from the surgeons in charge of a brigade or division hospital on a special requisition approved by the chief surgeon, and that no receipt is to be given for articles that may be expended. On the supply list the names of expendable articles are printed in roman type, those of unexpendable articles in italic. The table gives also the provision made for a brigade or division hospital including medicines, antiseptics and disinfectants, hospital stores, stationery, surgical instruments, appliances and dressings, furniture, bedding and clothing and miscellaneous articles, with surgical chests Nos. 1 and 2, a case containing an Arnold's sterilizer and a Berkefeld filter, a field operating case, a mess chest, a food chest, a commode chest and a set of folding field furniture.

Water-Supply at Tampa, Fla.—Articles have appeared in the daily press in relation to the unwholesomeness of the water-supplies furnished to the troops recently aggregated at points in the South. It is gratifying, therefore, to learn from an official source that at one of the points of concentration the supply is abundant and excellent. Dr. G. H. Altree, city health officer, Port Tampa City, certified in a circular letter dated May 9, 1898, that in his observation during five years no inhabitant of that city has suffered in any way from the use of the water-supply.

During the years 1896 and 1897 the absolute number of deaths in the city was twenty-eight, eight of which resulted from accidents, leaving twenty due to all other causes. Not one of these deaths was occasioned by diarrhea or dysentery. An analysis of the city's drinking water by Prof. Geo. F. Payne, State Chemist, Atlanta, Ga., shows that although the water is somewhat hard owing to the presence of about seven grains of lime carbonate per gallon, it is perfectly free from organic matter. It yields no free ammonia and only .01 part of albuminoid ammonia per million parts of water. An analysis by Prof. A. A. Persons, State Agricultural Institute, Lake City, Fla., gave almost identical results.

Canned Salmon for Army Use.—The Subsistence Department of the Army has under consideration the advisability of issuing canned salmon in place of dried fish as an article of the soldier's ration and as a change from bacon when fresh beef is not available. Weight for weight, the canned salmon compares satisfactorily with fresh beef. Its calorific value is somewhat lower than that of beef on account of a smaller percentage of fat, but its muscle-forming material offsets this, particularly as a food in warm climates. A comparison of the analyses of salmon and sides of Texas beef, such as is usually issued at army stations, as given by Prof. W. O. Atwater in his "Clinical Composition of American Foods," Bulletin 36, U. S. Department of Agriculture, shows the average percentage of proteids in salmon, 19.5, and in beef, 14.6; fat, 7.5 and 16.0; refuse, 14.12 and 18.3, and water, 56.8 and 50.04. Of all canned goods salmon has the reputation of being that which has most frequently occasioned gastro-intestinal troubles; but this has little weight as an argument against its use when we consider the infrequency of such troubles and the immense amount of canned stuffs used annually by the population. There is no doubt the change will be accepted by the troops as giving an agreeable variety to the field ration.

The Mauser Rifle, the Spanish Arm.—It is believed that the Mauser rifle, as modified by the Spanish military authorities and used in the Cuban war by the royal troops, is a weapon better adapted for wounding than for killing, especially at short range. The bullet is one-third of an inch in caliber, conico-cylindric in shape, wrapped in five coverings, the outer of which is made of nickel-plated steel. With a charge of twenty-eight grams of smokeless powder the range is 2000 meters, and at 100 meters the bullet can pierce a meter of pine wood. Dr. J. S. Fernandez has described a case of Mauser gunshot wound in the *Cronica Medico-Quirurgica*. The patient, aged 41 years, was wounded in the left temple, the bullet traversed the frontal lobe of the brain obliquely, and escaped just above the inner canthus of the left eye. Immediately on receiving the injury the man fell to the ground, but after recovering from the shock he did not complain of pain. The eyelids became swollen and pressed down on the eyes, excluding light. After eight days the swelling diminished and then it was noticed that the globe of the left eye had become much smaller and that the sight of that eye was lost. Neither pain nor suppuration had followed the injury and the sole lesion discernible was atrophy. The surgeon, in commenting upon the great velocity of the bullet, considers that in its passage through the tissues it cauterizes those with which it comes in contact; hence the primary hemorrhage is slight, but secondary hemorrhage frequently occurs, probably from slight sloughs from the cauterized walls of the injured blood vessels. The destructive power of the weapon is well shown by Dr. Antonio Canello y Peirole's case of a soldier who was cleaning the barrel of his loaded rifle. He had placed his left wrist on the muzzle and by some accident the rifle went off; the bullet entered the anterior surface of the wrist and passed out at the posterior surface at the carpo-metacarpal articulations. It blew away the car-

pal extremities of the radius and ulna: the whole of the os magnum, semilunar and unciform bones, and the carpal ends of all the metacarpal bones. On examining the wound with the finger it was found to contain a large number of spicula of bone, some loose and some only partly detached. The hemorrhage was slight. Under strict aseptic dressing the hand was saved, but not without much trouble. On the fourth and fifth days the patient complained of much pain, had a high temperature and was restless. On the tenth day there came a copious discharge of pus, and on the twelfth day the temperature was normal, the pus lessened and the patient made an uninterrupted recovery.

Footwear for Soldiers.—Wellington was ever deeply anxious that his men should be well shod. "What is the most essential thing for a soldier?" asked a member of the government of the Duke of Wellington. "A good pair of boots to begin with," replied the hero of Waterloo; "and in the next place a second pair of boots; and thirdly, a spare pair of soles." Alexander's victorious army reached India on sandals, and to this day a similar flimsy foot-protector is generally worn in eastern countries, but the ideal boot for a modern soldier should be impervious to moisture, stout and yet pliable, accurately shaped, and constructed of the most durable material. It should also be easily put on and taken off, should prevent the entrance of dust, sand or mud, and above all, favor the free play of each pedal articulation, while at the same time affording support to the muscles of the foot and ankle collectively. An ill-fitting, clumsily shaped boot is worse than none at all. Undue pressure or friction at any point quickly leads to corns and lameness. Formerly bunions and ingrowing toenails, due to pointed boots and shoes, were causes of a halting gait amongst the population generally, but of late years more attention has been given to the anatomic features of the foot, especially in growing children. Deformed feet are, however, still of frequent occurrence in the ranks, each case demanding special treatment; but it should be an invariable axiom with officers commanding companies that boots should be made to fit the feet and not vice versa. The following recipe for making boots both soft and waterproof was recommended by Edmund Parkes, and it still holds first place: "Take half a pound of shoemaker's dubbing, half a pint of linseed oil, half a pint of solution of India-rubber; melt together with care and rub in firmly." The India-rubber solution is highly inflammable, requiring attention during the melting process. The *Daily Mail* says, "It is always the same story, knavery and slackness clogging and strangling the best efforts of the British soldier. To save somebody a few pence on a boot you stand to lose a good rifle and bayonet in a decisive battle, and to break a good man's heart into the bargain. Is it worth it? But it is always happening; the history of the army is a string of such disgraces; and each time we arise and bawl 'Somebody ought to be hanged.' So says everybody. And nobody ever is hanged."

The Medical Staff at the Front.—It is difficult at the present time to keep track of the appointments to prominent positions in the Medical Department of the Army and of the movements or assignments of officers. So far as we have been able to note, Colonel Chas. R. Greenleaf, Assistant Surgeon-General, U. S. A., has been assigned to duty on the staff of General Miles as Chief Surgeon of the Army in the Field. During the past week he has been engaged in superintending the organization of the medical department of the troops at Chattanooga, Tenn. Major William H. Daly (Pittsburg, Pa.) has been assigned to special duty with Col. Greenleaf on the staff of the General Commanding. Lieut.-Col. H. Lippincott, U. S. A., has been placed as Chief Surgeon on the staff of General Merritt, commanding the expedition to the Philippine Islands. Major W. H. Corbusier, formerly on duty at Angel Island, Cal.,

is to accompany Col. Lippincott as Acting Medical Purveyor for the expedition; and Capt. W. O. Owen, Capt. Ed. R. Morris, Capt. Thomas U. Raymond, Lieut. Henry Page, all of the U. S. Army, and Acting Assistant Surgeon Geo. H. Richardson have also been directed to report to General Merritt. At Chickamauga, Ga., the 1st, 3d and 6th Army Corps are concentrated under Generals John R. Brooke, James F. Wade and Jas. H. Wilson, respectively. The Chief Surgeons of these three corps are Lieut.-Cols. Rush Huidekoper, John Van R. Hoff and Nicholas Senn, U. S. Vols. Major E. T. Comegys, U. S. A., has been ordered from Fort Sill, Oklahoma, to Chickamauga as Acting Medical Purveyor for the troops in camp. At Tampa, Fla., are concentrated the 5th Corps, General Wm. R. Shafter, the 7th Corps General Fitzhugh Lee, and the Cavalry Division, General Joseph Wheeler with Lieut.-Cols. Benjamin F. Pope and Louis M. Maus, U. S. Vols., and Major Valery Havard, U. S. A., as Chief Surgeons. Major L. W. Crampton and Capt. J. T. Clarke, U. S. A., have been sent to the 5th Corps. Acting Assistant Surgeons Fred J. Combe, Samuel W. Stiles and Wilfred Turnbull are serving with troops at Tampa, and Acting Assistant Surgeon F. A. E. Disney is serving at Fort Jefferson, Fla. Capt. W. P. Kendall has been ordered from Fort Bronson, Texas, to duty with the 9th Cavalry at Tampa. The 4th Corps is concentrated in the neighborhood of Mobile under General John J. Coppinger with Lieut.-Col. R. M. O'Reilly, U. S. Vols., as Chief Surgeon. Capt. C. B. Ewing, U. S. A., is on duty with the 5th U. S. Cavalry at New Orleans, La., and Acting Assistant Surgeons Maynard, J. Burgess and Arthur Jordan with troops at Mobile. The 2d Corps is in camp near Falls Church, Va., under the command of General Wm. M. Graham with Lieut.-Col. Alfred C. Girard as Chief Surgeon. No other assignment of medical staff officers has as yet been made to this Corps. Acting Assistant C. L. Anderson has been ordered from Hagerstown, Md., to Newport News, Va., for duty with Light Batteries of Pennsylvania artillery. The General Hospital at Key West, Fla., is under the command of Major Wm. R. Hall, U. S. A., who has with him Capt. H. A. Shaw, U. S. A., and Acting Assistant Surgeon E. A. de Lipsey. The hospital at Fort Myer, Va., has Major W. B. Davis, U. S. A., as surgeon-in-charge, who has with him Acting Assistant Surgeon S. Melville Waterhouse. The general hospital at Atlanta, Ga., has Major Blair D. Taylor, U. S. A., as surgeon-in-charge, with Acting Assistant Surgeons Edgar A. Vander Veer and Edwin W. Patterson to assist him. The hospital at Fort Thomas, Ky., has Lieut.-Col. W. H. Gardner, U. S. A., as surgeon-in-charge, with Acting Assistant Surgeons David Baker and Burke L. Johnson to assist him. The hospital ship *Relief* is under the charge of Major George H. Torney, U. S. A., who has as assistants Acting Assistant Surgeons Llewellyn P. Williamson, Francis Metcalf, Randolph M. Myers and Joseph M. H. Henry. The appointment of certain immune Acting Assistant Surgeons has also been reported as Drs. Edward Bragg, M. G. Burgess and Roger P. Ames, ordered to Mobile; W. E. Parker, H. W. Danforth, W. W. Calhoun, H. P. Jones, B. C. Leonard, G. M. De La Torre, W. P. Lawrence, Robert N. Pitts, and Hosea M. Delgado ordered to Tampa; F. S. Dabney, Jos. A. Tabor and A. R. Booth to New Orleans, La. Announcement has also been made of appointments as follows: To be chief surgeons with the rank of major, Clayton Parkhill of Denver, Colo.; Herbert W. Cardwell, Surgeon General of Oregon; James H. Hysell of Pomeroy, Ohio; Henry F. Hoyt of St. Paul, Minn.; Jefferson D. Griffith of the National Guard of Missouri; R. Emmet Giffen of New York; E. Boeckmann of Minnesota; Thomas S. Kimball of Marion, Ind.; Charles B. Nancrede of the University of Michigan, John M. G. Woodbury of New York, Lewis Schooler of Iowa; George Cook of Concord, N. H.; Jas. M. Jenne of Vermont; Leonard B. Almy of Connecticut, and Thomas Earle Evans of Woodward, Ala.

Lord Lansdowne on the British Medical Staff Corps.—At a banquet given in honor of eminent members of the medical profession of Great Britain, at the Mansion House, May 4, 1898, Lord Lansdowne, Secretary of War, is reported by the *Daily Chronicle* to have said: "There is no department in the public service which owes more to, and depends more upon, the members of your profession than the army. With every year that passes the engines of destruction are brought to a greater pitch of perfection. The wounds which could now be inflicted in a few seconds are more numerous and more serious than could have been inflicted in the same number of hours, not many years ago. Your skill and devotion are the correctives of our modern ruthlessness. I am using no idle phrase when I say that the army is proud that it contains a number of officers who belong to the medical profession, but who are none the less soldiers in the fullest sense of the word, wearing the Queen's uniform, holding Her Majesty's commission, ready to take their share or more than their share of the risk and hardship of warfare. We are determined that there shall be no failure, either in theory or practice, to treat them with the respect to which they are entitled. I insist upon this point, because I have observed with very keen regret that there has existed for some time past a certain estrangement between the army and the profession. This want of confidence has had for its result that we have been unable to attract to the service the number of candidates, and I am afraid I must add, the class of candidates, whom we should like to see serving in the medical staff. I will not attempt to diagnose the case. Some of the symptoms are puzzling and obscure. It is possible that in this case, as in many others in which reasonable people have agreed to differ, mistakes have been made on both sides. We on our side are determined that you shall have no cause of complaint of us. We have already shown by our action in dealing with several points to which you have called our attention that we were prepared to redress any injustice where you were able to satisfy us that injustice had been done. We are now about to deal, and to deal thoroughly, with a question with regard to which not only the medical staff of the army, but the medical profession generally, feels most strongly. I mean the rank and status of the Army Medical Staff. I sometimes hear it said: 'What does rank matter? Is not the title of doctor or surgeon by itself to be regarded as a title which any one should be proud to wear without further adjuncts?' I think the answer to that is, that in the army rank is the outward and visible sign of consideration and authority, and that although 'a man may be a man for all that,' it is necessary if he adopts the military profession, that he should have a military stamp to distinguish him and to secure him his proper place among his comrades. We have attempted several times to deal with this question of rank, as it affects the army doctors, and we have not been particularly successful. We have invented ingenious compromises which satisfied nobody, and titles of which some would, for cumbrousness and cacophony, be hard to heat. We propose to make a fresh start and to form out of the Army Medical Staff and the Medical Staff Corps a corps of officers bearing the same military titles as other officers of the army, always, of course, upon the clear understanding that those titles do not confer any right to command outside it. We propose to give them these titles up to the rank of colonel. I have been pressed not to stop there, but to go on to the rank of general officer; but there are reasons which seem to me conclusive against doing this. Our present policy is to restrict as closely as we can the number of officers bearing the title of general, and to insist that none shall rise to that rank unless he is required to fill one of a limited number of appointments, all of which will involve general command in the army and fitness on occasion arising to command troops in the field. No departmental officers will, under this system, be able to reach the rank of general officer, and it will be im-

possible for us to confer it upon members of the medical staff. Above the rank of colonel we propose to retain that of surgeon-general, with the rank and precedence of a general officer in the army. I have one thing to add. Her Majesty, upon whose good will toward your profession I need not dwell, has been pleased to signify her intention of bestowing upon the newly formed corps the title of Royal Army Medical Corps, a title which I am sure it will wear worthily. I trust that the members of the profession will recognize the sincerity with which we have endeavored to meet them, and that they on their side will help us, to the utmost of their ability, to secure the services of the best of their students." Sir William Mac-Cormac, responding to the toast of the Houses of Parliament, said he desired on behalf of his surgeon brethren to say how greatly they appreciated what had fallen from the Minister of War. In the face of great difficulties he had conceded all that the Medical Department and its friends in civil life had desired for it.

New Publication.—The *New Hampshire Sanitary Journal*, edited by Irving A. Watson, M.D., Concord, N. H., began publication with the May number. "The primary object of this journal is to advocate the public health interests of New Hampshire," it is also to be of practical value not only to health officers, but to all classes.

Tablet Erected to Two New Jersey Physicians.—At the annual meeting of the Camden County (N. J.) Medical Society, held at Blackwood, N. J., May 10, a large Tablet of brass was erected in the Camden County Almshouse, bearing the following inscription artistically engraved:

IN MEMORIAM.

This Tablet commemorates the services of
Dr. Joseph Wesley McCullough
and

Dr. Henry Ely Branin,
during the epidemic of Typhus Fever in the
Camden County Almshouse

from November 24th, 1880, to April 9th, 1881, when there occurred 103 cases with 33 deaths, including that of

Dr. McCullough.

The history of the Medical Profession of this Country affords no greater instance of unfaltering courage and heroic devotion to duty than was exhibited by these public servants, during this epidemic.

Erected by

The District Medical Society
Of the County of Camden, New Jersey,
May 10th, 1898.

The speech of presentation was made by Col. E. L. B. Godfrey, Assistant Surgeon General of New Jersey, and that of acceptance by the Hon. Henry F. Wolfe, Director of the Board of Chosen Freeholders of Camden County. After the exercises, the Society was entertained at a banquet by the Board of Freeholders.

New Medical School's Faculty.—President Schurman of Cornell University has announced finally the faculty appointments in the new medical college in New York City, for which medical and scientific men all over the country have been anxiously looking for some weeks past. The list is as follows: Alexander Lambert, Professor of Clinical Medicine, Instructor in Physical Diagnosis; Charles E. Namack, Professor of Clinical Medicine; Francis W. Murray, Professor Clinical Surgery; George T. Elliot, Professor of Dermatology; Charles Stedman Bull, Professor of Ophthalmology; Allen McLane Hamilton, Professor of Mental Diseases; William F. Stone, Instructor of Anatomy, Assistant Demonstrator of Anatomy; George D. Hamlin, Instructor in Gynecology and Obstetrics; Louis W. Riggs, Ph.D., Instructor in Chemistry, Physics and Hygiene; Percival R. Bolton, Instructor in Surgery; Warren Coleman, Instructor in Clinical Medicine and Materia Medica; Lewis A. Connor, Instructor in Medicine; John Rogers, Instructor in Surgery, Assistant Demonstrator of Anatomy; Benjamin T.

Tilton, Instructor in Surgery; Edmund Pendleton Shelby, Instructor in Materia Medica Laboratory; Dever S. Byard, Instructor in Medicine; Edward L. Keyes, Assistant Demonstrator of Anatomy; Charles C. Barrows, Clinical Instructor in Gynecology; Bertram H. Buxton, Instructor in Bacteriology; J. E. Winters, Professor of Diseases of Children; Newton M. Schaffer, Professor of Orthopedic Surgery; Gorham Bacon, Professor of Otolaryngology; William Sickles, Assistant Professor of Chemistry and Physics; C. N. B. Camac, Instructor in Clinical Microscopy.—*N. Y. Commercial Advertiser*.

Hospitals.

THE FOURTH large city hospital in Berlin will be completed in 1903. Over thirteen million marks have been appropriated for it and it is expected to be a model in every respect, with 62 different buildings, mostly one story, and 650 beds, and all the modern appliances for hydro- and movement-therapeutics, etc. It is located in the extreme northern part of the city, with large grounds. The Koch Institute is to be incorporated with it in four separate buildings. As in all large establishments of the kind there will be two medical superintendents, one university graduate administration superintendent and four pharmacists, with an assistant physician to every fifty patients.—*Pharm. Ztg.*—By the will of the late William Keiath of Philadelphia \$1500 was left for the erection of memorial beds at the German Hospital, to be known as the William Keiath, Sarah Keiath and Julia Keiath memorial beds.—The new Georgetown University Hospital, corner of Thirty-fifth and N Streets, Washington, D. C., which has been in course of erection since May, 1897, has practically been completed, with the exception of the interior furnishings. It has a frontage of sixty feet on N Street and a depth of fifty feet. It is four stories and basement in height and built of red brick. It is estimated that, completed, it will cost upward of \$30,000.

Colleges.

THE SCHOOL OF MEDICINE of Georgetown University, Washington, D. C., held its forty-ninth annual commencement May 16, with a graduating class numbering seventeen.—The degree of M.D. was conferred on 103 students by the Medical College of New York University, May 18.—The thirty-ninth annual commencement of the Long Island College Hospital, Brooklyn, was held May 18, with a graduating class of seventy-two members.—The graduating class of Rush Medical College, Chicago, at the fifty-fifth annual commencement May 25, the first since the affiliation with the University of Chicago, numbered sixty-six.—The University College of Medicine, Richmond, Va., held its annual commencement May 26.—At the commencement of the Woman's Medical College of Philadelphia, held May 19, the degree of M.D. was conferred upon thirty-four students. Nine States and three foreign countries were represented among the list of graduates.—There were one hundred and thirteen graduated at the annual commencement of the Medico Chirurgical College, Philadelphia, May 21.—Jefferson Medical College, Philadelphia, is to have a new building on Tenth and Walnut Streets. The greater portion of the structure will be five stories, a portion six, and in the Italian renaissance style of architecture.

Societies.

The following recent meetings are noted:
Connecticut.—Connecticut Medical Society, 106th annual meeting, New Haven, May 25 and 26.
Illinois.—Chicago Medical Society, May 25 and June 1; Fox River Valley Medical Association, Elgin, May 24.
Iowa.—Iowa State Medical Society, Des Moines, May 18, 19 and 20.
Kentucky.—Southern Kentucky Medical Association, Hopkinsville, May 24 and 25.
Maryland.—Baltimore County Medical Association, Towson, May 19.
Missouri.—State Medical Society, Kansas City, May 24-26; St. Louis Medical Society of Missouri, May 28.
New York.—Monroe County Medical Society, Rochester, May 25; Washington County Medical Society, Argyle, May 17.

North Dakota.—State Medical Society, Jamestown, May 25 and 26.

Ohio.—Academy of Medicine, Mansfield, May 16; Belmont County Medical Society, Bellaire, May 27.

Pennsylvania.—State Medical Society, Lancaster, May 17-19; Venango County Medical Society, Franklin, May 24.

Tennessee.—West Tennessee Medical and Surgical Association, Jackson, May 19.

Cincinnati.

At the regular meeting of the Academy of Medicine, May 16, a paper was presented by Dr. Gustave Zinke, on "Complicated and Difficult Labor." He reported three fatal cases with most complete and careful histories. Case 1. Puerperal eclampsia. Case 2, Post-partum hemorrhage complicated with nephritis. Case 3, Frontal presentation with prolapsed extremities, complicated with puerperal mania. Discussion was by Drs. Stanton, Kiely, Stewart, Fraid, McLean, Reamy, and the essayist. Dr. O. P. Holt reported a case of dilated and hypertrophied heart due to excessive use of tobacco: Male, 38, soapmaker, has been chewing tobacco for the last twenty-one years. During the last seven years he has used on the average three ounces of tobacco a day; smokes and drinks (beer) moderately; denies venereals and there are no evidences of syphilitic infection; has never had any rheumatism; no sudden strain thrown on his muscular system or upon the heart, nor has he ever been in any occupation necessitating undue exertion; has never indulged in athletics. He entered the Cincinnati Hospital over a month ago, complaining of his heart and stomach. Physical examination shows him to be well developed and fairly well nourished; eyes normal, ophthalmoscopic examination negative, no contraction of the field of vision; lungs normal; apex beat in the seventh intercostal space displaced as far outward as the anterior axillary line; beat forcible, diffuse, vibratory so as to somewhat resemble systolic retraction, but palpation determines that such is not the case; heart's action irregular as shown at apex and by pulse. Heart's action and pulse correspond; the area of superficial dulness resembling that of aortic incompetency; to the right it extends about an inch to the right of the sternum while the apex as said before is situated in the anterior axillary line; auscultation, no bruits, both sounds loud and ringing all over cardiac area, irregular action marked; liver and spleen not enlarged; urinalysis, negative. During his entire stay in the house no murmurs have been detected at any time. The urine has been examined every day and no albumin or sugar has been present at any time; average specific gravity, 1020; no casts on repeated microscopic examination. Blood, reds, 4,200,000; whites, 7500; h'm., 78 per cent. Sphygmographic tracings show quick rise though short, and long slow descent with slight diastolic at about the center. With the history and symptoms, Dr. Holt could not but look upon the case as one of tobacco heart.

ACADEMY OF MEDICINE, May 24.—Dr. J. A. Thompson, reported a case of sarcoma of the naso-pharynx, in a child 4 years of age, which had extended down behind the tonsil so as to become readily visible. This condition had been noted by the parents two weeks before the case came into the hands of a physician. The child had had several severe attacks of dyspnea, and was only saved from death by suffocation by the almost constant attendance of the family physician. A week from the time first seen, the tumor had reached a very large size, and for the relief expected by the removal of the mass more than for any hope of any permanent cure, an operation was advised. The growth was encapsulated and was in great part removed by the cold snare, the child being of course anesthetized. The gross specimen was exhibited and the microscopic report proved the clinical diagnosis that the tumor was a small rounded sarcoma. Attention was also called in this connection to the extreme variability in malignancy of malignant growths of this region. He seven years ago removed a carcinoma from a patient, first union had resulted, and no recurrence had been

noted until a few weeks ago, when operation and microscopic examination had again proved a carcinoma. The regular paper of the evening, entitled "Lymphatic Leukemia with Report of a case of Pernicious Anemia," was read by Dr. G. A. Fackler. He called attention to the advances made in hematology during the past decade, laying especial stress upon the absolute certainty with which a diagnosis could be made by attention to this tissue alone regardless of clinical symptoms; that this was true as regards lymphatic leukemia, which clinically greatly resembled many cases of Hodgkin's disease; that in lymphatic leukemia, in which like in all forms of anemia, there was a varying diminution in the number of red cells, the diagnosis rested upon the high grade of permanent leucocytosis, usually the white corpuscles averaging 100,000 per cubic millimeter. This increase was mainly in the young cells, the so-called lymphocytes, which contributed in place of their usual 20 to 30 per cent., fully 90 per cent. of the entire number. The adult cells or polymorphonuclear neutrophiles while absolutely increased were relatively diminished, while the myelocytes so common in the splenomyelogenous leukemia, were extremely scanty in the variety under consideration. He recognized but two varieties of leukemia, the spleno-myelogenous and the lymphatic, pure splenic and pure myelogenous being so rare as scarcely to warrant consideration. He wished to speak mainly of the clinical features of his subject, leaving out mention of etiology and pathology because of the chaos that reigned at present in these branches of the disease. In the spleno-myelogenous form the permanent leucocytosis was much greater as a rule than in any of the cases of the lymphatic, averaging over 400,000, while the principal point was the presence of abnormal white corpuscles known as myelocytes, occupying about 30 per cent. of the field. These two forms were also well separated clinically; the lymphatic was usually characterized by but slight enlargement of the spleen, and by general glandular enlargement; it usually occurred in the young and ran, as a rule, an acute course from six weeks to three months. The spleno-myelogenous, on the other hand, was recognized by the enormous enlargement of the spleen, almost filling the entire abdomen; the glands were not usually enlarged and the course was chronic. Where the blood showed a combination of the two types, the clinical symptoms also varied to meet these altered conditions. In pernicious anemia, the diagnosis was reached by the marked diminution of the red corpuscles, averaging 1,200,000; but the blood was subject to considerable variation, often great increase over this number without apparent cause; high color index, diminution in the number of white cells, irregularity in size and shape of the red cells and especially the presence of nucleated reds both normoblasts and megaloblasts. The latter when in excess of the former always indicated an unfavorable prognosis. The treatment usually directed was arsenic in gradually increasing doses of Fowler's solution; this was the only remedy as far as he knew that exerted any favorable influence on the disease, and in spite of this the cases usually ended fatally, though the fatal termination was often preceded by periods of improvement. The paper was discussed by Drs. Cleveland, Greiwe, Kramer, Schenck, Keily (the difference between chronic malaria and leukemia), Joseph Eichberg, H. M. Brown (the relation of nervous troubles, especially cord lesions, to pernicious anemia).

SOCIETY OF MEDICAL RESEARCH.—Regular meeting was held May 12, with presentation of specimens and discussion of: "Fibrous Pneumonia," by Drs. Whitacre and Eichberg. "Malignant Adenoma of the Naso-pharynx," "Tuberculosis of the Nasal Septum," by Dr. Freiberg, "Plugging of Cerebral Artery," Dr. Zenner. "Urine Crystals," Dr. Crane.

HEALTH DEPARTMENT, April.—Measles, 52 cases, no deaths; diphtheria, 19 cases, 5 deaths; scarlet fever, 20 cases, no deaths; typhoid fever, 19 cases, 4 deaths; phthisis pulmonalis, 67 cases, 66 deaths; membranous croup, 8 cases, 1 death; pertussis, 76 cases, 18 deaths; varicella, 8 cases, no deaths; variola, 1 case, no deaths. Diseases causing greatest mortality: Pneumonia, 70; phthisis, 66; heart disease, 37; bronchitis, 32; meningitis, 22; whooping-cough, 18; apoplexy, 18; accidental, 18. From all causes there were 518 deaths for the month. Of the outdoor poor there were 475 treated, 1722 visits paid, and 13 deaths recorded.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY.—The regular meeting, was held May 19. Judge Wm. L. Carpenter read a paper on "Malpractice," confining his address as closely as possible to the legal interpretation of the term malpractice. Dr. H. O.

Walker led the discussion, treating the question from the standpoint of a physician. He gave it as his opinion that it was fair to presume that the surgeon or doctor who finds himself the defendant in a suit for malpractice is in every case the victim of greed, and unfortunately is often at the mercy of a stupid jury or a prejudiced judge. The Doctor stated that he knew a number of instances where the defendant was mulcted in heavy damages, though he was certainly not at fault in the treatment of the case in question. Thos. Hislop, attorney at law, read a paper on "Expert Testimony," followed on behalf of the medical profession by Dr. Leartus Connor. The Doctor stated that he had decided a number of years ago never again to appear as an expert witness, giving as his reason that the present methods in legal investigation are so unscientific and besides so revolting to the witness that they are to be condemned. He then went on to give a full description of what would, in his estimation, be a rational and scientific method of taking expert testimony, or rather of obtaining expert information in a given trial. As it is now, he declared, each lawyer is desirous, not of seeing justice done, but of "winning his case." His proposed system is to have the expert witness confer with the court and with the attorneys as an adviser, imparting such information as he has, by long and patient industry obtained, and which is not possessed by the legal profession nor by any ordinary witness. Attorney Alfred Lucking followed with an address on "Physicians' Privileges in Giving Testimony," the substance of which was that a physician can not be compelled to answer a question in giving testimony by which he would divulge any secret he may have obtained in a professional way, except in the case of any person who has waived his right to the provision.

At the regular meeting, May 26, S. E. Sanderson read a paper entitled, "Senile Gangrene or Renaud's Disease—Which?" The author reported a unique case of gangrene involving the toes and integument of the foot and lower two-thirds of the leg, in a lady 72 years of age, which resulted in recovery to health with loss of only four of the toes at the metatarsophalangeal articulations. The case presented many features of an interesting character. The age of the patient, the heart trouble, which, though not organic, was serious enough to produce oppression, and the beginning atheroma of the arteries pointed to senile gangrene. But the history of the disease, beginning by syncope of the blood vessels of the leg and foot succeeded by cyanosis and gangrene, each following the other in rapid succession, and the presence of hemoglobinuria and the complete recovery, would make one incline to the diagnosis of Renaud's disease. E. B. Smith read a paper on "Surgical Tuberculosis of the Skin and Other External Organs." He stated that surgery of the skin narrowed itself down to such simple procedures as curettage, scraping or, at most, extirpation of the affected area, followed by skin grafting or flap operation. He referred to the tuberculous diseases of the eye, ear and nose, and gave their diagnostic features and chief methods of treatment. Tuberculous ulcer of the rectum and anus he described as of two kinds: 1. Those which occur in persons suffering from tuberculosis of the lungs and which contain no bacilli. 2. Those occurring as typical tubercular ulcerations primarily. The treatment for the latter is early extirpation. F. D. Summers exhibited the excised tubes of a lady aged 19 years, who had been infected with gonorrhea some time before operation. The doctor had removed the tubes, but the abdominal wound had never closed, and during her menstrual flow blood had escaped through the sinus. The Doctor reopened the wound and found that the stump of the tube had attached itself to the abdominal wall at the sinus. This was removed and the patient recovered. Incidentally at the second operation, the Doctor discovered and removed a large cyst of the broad ligament of the opposite side.

HEALTH REPORT for the week ending May 28: Deaths 84;

under 5 years 31. Births, male 37, female 41; contagious diseases, diphtheria none. According to the Health Office this is the first time in twenty-five years that the city has been free from diphtheria. Scarlet fever 17; deaths from diphtheria 1; scarlet fever 1.

Consolidation of Bellevue and New York University.—The union of these institutions was announced by Chancellor MacCracken of New York University at the annual commencement of the Medical College of the University, May 18, when he read the following: The following action was unanimously adopted by the New York University Council on Monday, May 16, being presented by Mr. William A. Wheelock, on behalf of the committee preparing the same:

The Council of New York University regret to be obliged to announce that by reason of the failure of some of our professors of medicine since May 26, 1897, to observe the duties belonging to their relation to us under the University system, as interpreted by the Council, we were constrained to condition their continuance as permanent professors upon their acceptance of existing University rules and requirements. The six professors who belonged to the governing faculty have rejected this offer, and accordingly will cease at the end of this college year to be connected with New York University.

The Council have further maintained that they are beyond all possible question the rightful successors of the trustees of the Medical College Laboratory, and are the only proper persons to execute that trust. Yet they have offered without reserve to submit all questions involving our equity in the entire medical property used by us to arbitration. This offer has been rejected.

We here record as a subject of equal surprise and regret to this Council that a sister University some weeks ago began negotiations looking to the establishment of a new medical school in this city, with what was plainly a combination of professors at variance with their own University, and this without any consultation with this University and without the slight delay which would have enabled these professors decently to tender their resignations of their present professorships.

The Council further announces that the trustees of the Bellevue Hospital Medical College have today voted to complete the consolidation of that college with New York University. The strength of these two venerable foundations will henceforth be given to a single medical school under the title of "The University and the Bellevue Hospital Medical College." The alumni of the two schools, numbering nearly ten thousand graduates, will be placed on the rolls of the University. The two properties, together occupying 225 feet front in East Twenty-sixth st., near First ave., and costing about \$500,000, will be owned by the New York University and used by the united school.

The faculty of the new school will consist of Dr. Edward G. Janeway, dean, and seven professors of the former University Medical faculty, and twenty-one professors and adjunct professors of the former Bellevue Medical faculty, together with such additional professors as may hereafter be appointed. Besides these there are thirty or more lecturers, instructors and assistants. The complete roll of the faculty will hereafter be announced. *N. Y. Tribune.*

CHANGE OF ADDRESS.

Armstrong, V., from Indianapolis, Ind., to Whitecomb Building Pueblo, Colo.
Brown, M. M., from Pepin, Wis., to Golden, Ill.
Bronnell, W. F., from Chilton to New London, Wis.
Buckle, S. D., from Norristown, Pa., to Atlanta and Illinois Aves., Atlantic City, N. J.
Berry, B., from 3028 Locust St., to 3400 Morgan St., St. Louis, Mo.
Brown, G. V. L., from Duluth, Minn., to Milwaukee, Wis.
Butterfield, F. A., from 713 Ashland Ave. to 624 North St., Rockford, Ill.
Campbell, D. A., from Windsor, Ontario, to Harper Hospital, Detroit, Mich.
Carter, G. D., from St. Louis to New London, Mo.
Fredrick, C. C., from 35th and State to 3243 State St., Chicago.
Goldnamer, W. W., from 2308 State St. to 3454 Indiana Ave., Chicago.
Grieger, H., from Pueblo to 3132 Boulevard, Denver, Colo.
Gray, A., from 248 Winchester Ave. to 456 Ogden Ave., Chicago.
Homan, J. H., from Berlin, Germany, to Kesselsaer, Ind.
Hovender, J. H., from Lake View to Lawrence, Iowa.
Hodgkinson, C., from Detroit to 416 E. Cross St., Ypsilanti, Mich.
Hobday, Dr., from Louisville, Ky., to Marshall, Minn.
Homer, H. C., from Crain Creek to Horton, Iowa.
Hicks, J. M., from 171 E. Washington St. to 522 Massachusetts Ave., Indianapolis, Ind.
Johnson, H. C., from Columbia to Meadville, Mo.
Kennedy, W. U., from Winchester to Tallula, Ill.
Leresche, E. P., from 877 S. Spaulding Ave. to 1389 Ogden Ave., Chicago.
Layman, R. B., from Dandridge to Knoxville, Tenn.
Le Moyne, F., from Santa Barbara, Cal., to Pittsburg, Pa.

Malott, J. D., from Amboy to North Grove, Ind.
McFarland, J., from Philadelphia to 421 N. Price St., Germantown, Pa.
Moulton, M. W., from Maquoketa to Bellevue, Iowa.
Pry, E. T., from Knowlton to Tucker, Ark.
Russell, G. M., from Rock Springs to Dixon, Wyo.
Risjord, J. N., from Mt. Horeb, Wis., to Kensett, Iowa.
Reid, W. J., from 244 Alfred St. to 914 18th St., Detroit, Mich.
Rogers, O. L., from Baltimore, Md., to Milledgeville, Ga.
Sheldon, J. G., from Chicago, Ill., to New Haven, Iowa.
Seelye, T. P., from Chicago to Angola, N. Y.
Sherman, A. W., from 944 West Polk to 2400 Dearborn St., Chicago.
Stover, G. H., from 324 Jackson Bldg. to 319 McPhee Bldg., Denver, Col.
Sullivan, A. W., from Shiloh, N. J., to Phoenix, Ariz.
Snoddy, F. B., from 1414 H. St. N.W. to 1217 K St. N.W., Washington, D. C.
Sloan, J. F., from Chicago to 613 Wayne St., Peoria, Ill.
Thornton, A. H., from Pocahontas to West Bend, Iowa.
Toan, J. W., from Detroit to Portland, Mich.
Veasey, C. A., from 47 N. 17th to 116 S. 19th St., Philadelphia, Pa.
Wheeler, F. B., from Dows, Iowa, to Strawn, Kan.
Winn, G. B., from Brown Bldg. to Masonic Temple, Rockford, Ill.
Worley, H. F., from Lexington, to Pine Grove, Ky.
Wegge, W. F., from Oshkosh to 693 Cass St., Milwaukee, Wis.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from May 21 to 27, 1898.

Acting Asst. Surgeon Francis W. Harrell, U. S. A., will proceed from Washington, D. C., to San Francisco, Cal., and report in person to the commanding General of the expedition to the Philippine Islands for duty.

First Lieut. William E. Richards, Asst. Surgeon, having reported to the Surgeon-General in compliance with orders, will proceed to Mobile, Ala., and report in person to the commanding General, Fourth Army Corps, for duty in the field with the Fifth Cavalry.

Capt. Joseph T. Clarke, Asst. Surgeon, will proceed to Tampa, Fla., and report in person to Major-General William R. Shafter, U. S. Volunteers, for assignment to duty.

The following named officers of the Medical Department will proceed to San Francisco, Cal., and report for duty with the expedition to the Philippine Islands: Lieut.-Col. Henry Lipincott, Deputy Surgeon-General; Capt. William O. Owen, Asst. Surgeon; Capt. Edward R. Morris, Asst. Surgeon; First Lieut. Henry Page, Asst. Surgeon.

The following assignments of officers of the Medical Department are made: To First Army Corps, Lieut.-Col. Rush Hudekoper, U. S. Volunteers; to Second Army Corps, Lieut.-Col. Alfred C. Girard, U. S. Vols.; to Third Army Corps, Lieut.-Col. John Van R. Hoff, U. S. Vols.; to Fourth Army Corps, Lieut.-Col. Robert M. O'Reilly, U. S. Vols.; to Fifth Army Corps, Lieut.-Col. Benjamin F. Pope, U. S. Vols.; to Sixth Army Corps, Lieut.-Col. Nicholas Senn, U. S. Vols.; to Seventh Army Corps, Lieut.-Col. Louis M. Maus, U. S. Vols.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, JUNE 11, 1898.

No. 24.

ADDRESSES.

THE ADDRESS OF THE PRESIDENT.*

Delivered at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY GEORGE M. STERNBERG, M.D.

Fellow Members of the American Medical Association:

I desire at the outset of my presidential address to express to you my high appreciation of the honor conferred upon me and my thanks for the same. I esteem it a special honor to have been elected president of the American Medical Association at the semi-centennial meeting in Philadelphia. The large attendance, the hospitable reception accorded us by the citizens of Philadelphia, the admirable arrangements for our meetings, the high professional and scientific standard of the general addresses and of the papers read at the sectional meetings, all contributed to make this a memorable meeting, and it will be a matter of just pride in the future for those members who are able to say, "I was present at the semi-centennial meeting of the American Medical Association in Philadelphia in 1897." Possibly some of our younger members may have the privilege of attending the centennial meeting of the Association in 1947 and of giving testimony with reference to the success of the semi-centennial meeting and the status of scientific medicine at the close of the nineteenth century. If so, they will not fail to mention the fact that the founder of the Association, Dr. Nelson S. Davis, was present on this occasion and that the distinguished American surgeon, Nicholas Senn, was the presiding officer.

I congratulate you upon the favorable prospects for a pleasant and profitable meeting of the Association in this beautiful and hospitable city of Denver. I have had no doubts as to the success of the meeting over which I am called upon to preside since I heard the decision as to the place selected for our annual convocation. The invigorating air of this elevated region, the grand mountain scenery, and the inducements to activity offered by a State rich in mineral resources, all are conducive to physical and mental energy and to a broad-minded liberality, the results of which will no doubt be apparent in the arrangements made for the scientific work of the Association and for the entertainment of its members.

Our Association, as the representative body of American physicians, will no doubt continue to increase in membership and in influence. The day is perhaps not far distant when no reputable physician will be willing to confess that he does not belong to the American Medical Association and when no progressive physician can afford to do without our JOURNAL. And in order that every physician of good

professional standing may enjoy the privileges of membership I think it desirable that "Permanent Members" should be elected, upon application, without reference to their membership in "State, County or District Medical Societies" when they present satisfactory evidence that they are graduates in medicine of reputable standing in the profession and are willing to subscribe to the code of ethics of the American Medical Association. In other words, I would not exclude a reputable physician from membership because the State, County or District Medical Society to which he belongs declines to adopt our code of ethics. If he, individually, is willing to be governed by the regulations made by this representative body I see no good reason for rejecting his application for membership.

A liberal and progressive spirit will do much toward promoting the growth and influence of the Association. The medical profession in this country has suffered more from the ignorance of some of its members who hold diplomas from regular schools of medicine than from the attacks of those whom we call irregulars or quacks. Scientific medicine, being founded upon demonstrable truths, must in the end maintain itself and secure the confidence of the people. But when the results of scientific research are rejected through ignorance of the experimental data upon which they are founded, and the layman hears contradictory professional opinions about matters which the well informed knows to be definitely settled, he may be excused for not differentiating so sharply as we are disposed to do between regulars and irregulars. To maintain our standing in the estimation of the educated classes we must not rely upon our diplomas or upon our membership in medical societies, but must show ourselves superior in knowledge and in professional resources to the ignorant pretender or to the graduate of a medical school which is bound in its teachings by an untenable creed, adopted before the light of science had taught physicians to reject theories and the dicta of authorities in favor of truths demonstrated by modern methods of research. There are those who still speak of us as "old school physicians," ignorant apparently of the fact that scientific medicine is to a great extent of very recent origin, and that all of the great discoveries in relation to the etiology, prevention and specific treatment of infectious diseases, and nearly all the improved methods and instrumental appliances for clinical diagnosis and surgical treatment have had their origin within the ranks of the regular profession. While, therefore, we still have with us some "old school doctors," who have fallen behind the procession, the profession as a whole has been moving forward with incredible activity upon the substantial basis of scientific research, and if we are to be characterized by any distinctive name, the only one applicable would be "*the new school of scientific medicine.*"

*Owing to the arduous duties of his office Surgeon-General Sternberg was not present at the Denver meeting. His address was read by Dr. Col. Woodhull, United States Army.

Not that our science is complete, for we have still many things to learn and many problems which have thus far resisted all efforts at their solution; but we have learned how to attack these problems and no one any longer expects that they can be solved by the exercise of the reasoning powers and the facile use of the pen. The old saying has it that "the pen is mightier than the sword." This is no doubt true in politics, but in science the pen is a feeble instrument compared with the test-tube, the microscope, the chemical balance, etc. Nevertheless, I am about to advise well-informed physicians to make greater use of the pen, not for the elucidation of those problems which remain to be solved, but for the purpose of calling the attention of the non-medical portion of the community to the recent achievements of scientific medicine. It is a remarkable and lamentable fact that many persons belonging to the so-called educated classes are grossly ignorant as regards the present status of medical science. They not only speak of us as "old school doctors," but they entrust their lives and those of their children to pseudo-scientists who, taking advantage of popular interest in the great discoveries of the day, make extravagant claims as to the curative power of electricity, the X-ray, oxygen, ozone, or some wonderful microbe destroyer. Or, ignoring the exact knowledge which has been gained by experience and pains-taking researches with reference to the etiology of various diseases and the curative action of approved therapeutic agents, they accept the vagaries of the osteopath and the christian scientist as representing the latest development of scientific progress in medicine. The false assertions and claims of ignorant enthusiasts and conscienceless vampires, as a rule, pass unchallenged. Not only are they able to impose upon a gullible public through their published advertisements, but articles written by them or for them appear in the columns of reputable newspapers. The ever-present and irresponsible newspaper reporter espouses their cause through ignorance or for gain and their wonderful cures are related and copied from one paper to another without any competent critic raising his voice to show the fallacy of the claims. Again, positive denials of the value of the well-established achievements of scientific medicine are often made, unfortunately too often, by men who are authorized to attach the letters M. D. to their signatures. This leads to the frequent repetition of the old question as to "who shall decide when doctors disagree?" No matter how well a fact may be established by repeated experiment or by the common experience of the profession, some doctor may be found who, through ignorance or that obliquity of mental vision which characterizes the crank, will deny its truth. Thus, there are doctors who deny the value of vaccination, others who fail to recognize any value in results obtained by experiments on the lower animals, others who deny the etiologic rôle of well-known pathogenic bacteria, etc. As a result the anti-vaccination and anti-vivisection societies are able to fortify their position by quoting the opinions of medical men of more or less repute. But opinions are of no value when opposed to evidence, and it seems to me that those familiar with the evidence would do well to give to the public concise and comprehensible statements, suitable for publication in newspapers and popular magazines, setting forth the facts and the evidence upon which these facts are accepted by well-informed physicians.

But in doing so, great care should be taken not to make any assertions that are not based upon reliable data. A distinguished surgeon who has taken an active part in opposing the anti-vivisection bill introduced into the Senate of the United States through the influence of the Washington Humane Society, recently wrote me as follows:

I have been corresponding with Welch, Burrell, Bowditch and others in reference to the formation of a society for the distribution of literature and fostering the sentiment in favor of scientific research. I would be glad to have your own views in the matter. It has occurred to me that at the meeting of the various special societies and especially at the AMERICAN MEDICAL ASSOCIATION this spring it might be well to introduce resolutions indorsing the formation of such a society.

In reply to this letter I said:

With reference to your suggestion as to the formation of a society for the objects mentioned, I think the idea is a good one and shall be glad to aid you in carrying it out. I think we have given those who are opposed to scientific medicine too much rope in allowing them to publish all sorts of misleading statements without our taking the trouble to contradict them or to educate the people. If we had an association organized for the purpose of answering such false statements as have circulation in the newspapers much good might result. When this is left to individuals generally no action is taken, on account, perhaps, of the disinclination on the part of competent physicians to have their names attached to articles appearing in the newspapers lest they may be thought by their professional brethren to be seeking notoriety and be accused of unethical conduct. Certainly it seems to me that the profession has a duty to perform in this direction and I hope you will take some steps to bring about such an organization as you suggest.

In carrying out this plan care should be taken not to engage in controversy with individuals whose misleading statements we desire to correct, but rather to have a systematic plan for placing the truth before the public. For example, an article on the medical uses of electricity might show its limitations and call attention to the fact that it has no germicidal effect when currents are used which are not destructive of the living tissues. Reference might then be made to the unscientific nature of the evidence offered in favor of the curative action of electric belts, electric rings and the electropoise, which is described as "a little instrument which enables the system to take on oxygen freely from the atmosphere." I venture to quote from a paper entitled "Science and Pseudo-Science in Medicine," which I read before the Anthropological Society of Washington in 1896, in further illustration of the kind of missionary work in the education of the public which I think such an organization as has been proposed should undertake. Referring to the electropoise, I say:

The *modus operandi* of this wonderful instrument is more fully explained in the following published certificate (advertisement in *McClure's Magazine*):

One might conclude, from its name, that it was an electric battery. But it does not generate electricity and is in no sense a battery, belt, sole, or anything kindred to them. It consists of a small cylinder called a "polarizer," which is used in connection with the patient's body by means of a common electric cord. This polarizer causes oxygen from the atmosphere to be absorbed by the entire surface of the body with great rapidity, the strength of the absorption being regulated according to the ability of the patient to receive.

After a year's use we have this to say in its favor: 1. We have taken no medicine for the year. 2. All traces of la grippe and an old sunstroke trouble have disappeared and no symptoms of either remain. Once or twice, from severe overwork, we have found it necessary to hold up for a few days, but in no time for fifteen years have we been better than during the past year. Much of this we attribute to the use of the "Electropoise."

This notice of the "Electropoise" is without solicitation and entirely gratuitous. We do it for the good of the afflicted. We have no personal interest in it and are not paid for what

we say in its favor. Persons desiring further information can address the agent—Rev. Wm. McDonald in *Boston Christian Witness*.

"We would suggest to the Rev. Wm. McDonald that he try the following simple experiment: Having connected the 'polarizer' with his leg by means of the 'common electric cord,' let him place one hand over his mouth and nose, thus shutting off oxygen of the atmosphere from the lungs, which have been provided by nature to furnish the necessary supply of this gas. Now let him note by a watch how long the supply of oxygen 'absorbed from the entire surface of the body' will answer as a substitute for nature's method of supplying this gas. We venture also to suggest to the Rev. Wm. McDonald that 'all traces of la grippe and of an old sunstroke trouble' might have disappeared during the year if he had not used the Electropoise. Assuming that this certificate is genuine, it answers very well to illustrate the fact that educated men who have not been trained in the methods of scientific investigation often arrive at conclusions entirely unjustified by the evidence before them and by the dangerous use of the *post hoc ergo propter hoc* method of argument."

The fact that a considerable proportion of those who are sick from various acute or chronic ailments recover after a time, independently of the use of medicinal agents or methods of treatment taken in connection with this tendency to ascribe recovery to the treatment employed, makes it an easy matter to obtain certificates of cure for any nostrum which an unprincipled money-seeker may see fit to offer to a credulous public. If 10 in a 1000 of those who have used the alleged remedy believe themselves to have been benefited, their certificates will answer all purposes of exploitation and the 990 will not be heard from by the general public.

As was to have been expected, the X-ray has already been made a source of revenue by more than one pseudo-scientist. The following account of the *modus operandi* of its supposed therapeutic action has recently been published in the newspapers:

After the Crookes tube is excited by the coil the magnetic lines of force are projected down in the same manner as they pass off from a magnet, and traversing the intervening space, pass through the body down to the floor and back to the coil and tube again, completing the circuit.

The X-ray is electrostatic in character and of a very high potential. With every discharge from the Crookes tube oxygen is liberated in the body, as well as the surrounding atmosphere, which, combining with nascent oxygen, forms ozone.

It is due to the electrolysis produced in the body that we are able to destroy the bacilli in contagious disease, ozone being the most powerful germicide known.

We remark, first, that we do not fully understand why "the magnetic lines of force" are reflected back by the floor, "completing the circuit." Inasmuch as the X-rays pass through wood, this mysterious action of the floor appears to call for some further explanation.

We will pass by the ingenious explanation of the formation of ozone, as a result of the action of the X ray, to call attention to the mistaken statement that ozone is "the most powerful germicide known."

The experiments of Fränkel show that the aerobic bacteria grow abundantly in the presence of pure oxygen, and some species even more so than in ordinary air.

It was formerly supposed that ozone would prove to be a most valuable agent for disinfecting purposes, but recent experiments show that it is not so active a germicide as was anticipated, and that from a practical point of view it has comparatively little value.

Lukaschewitsch found that one gram in the space of a cubic meter failed to kill anthrax spores in twenty-four hours. The cholera spirillum in a moist state was killed in this time by the same amount, but fifteen hours' exposure failed to destroy it.

Ozone for these experiments was developed by means of electricity.

Wyssokowicz found that the presence of ozone in a culture medium restrained the development of the anthrax bacillus, the bacillus of typhoid fever, and others tested, but concludes that this is rather due to the oxidation of bases contained in the nutrient medium than to a direct action upon the pathogenic bacteria.

The conclusion reached by Nissen, from his own experiments and a careful consideration of those previously made by others, is that ozone is of no practical value as a germicide in therapeutics or disinfection.

Unfortunately lack of information relating to the definite results of scientific investigations is not confined to the non-medical members of the community. The statement above quoted to the effect that the X-ray, by electrolysis, produces ozone when passed through the body and that ozone is the most powerful germicide known, sounds very scientific, and having been made by one who has a legal right to attach the letters M. D. to his name, no doubt has been accepted as a reliable statement of fact by many educated people who have read the newspaper paragraph in which the statement occurs, which, having started in Chicago, was widely copied as an item of interest to the public in connection with the recent discovery of the remarkable properties of the X-ray.

Whenever any new discovery in medicine is announced some conservative physicians, and often men of reputation in the profession, are sure to commit themselves to a positive denial of the alleged fact. This occurred when the discovery of the tubercle bacillus was announced by Koch, it has occurred with reference to the treatment of diphtheria by antitoxin, and to the preventive treatment of hydrophobia by Pasteur's method. Yet these discoveries are based upon experimental evidence of the most unimpeachable character. To deny their reliability at the present day is simply to show ignorance of the nature of this evidence or a failure to appreciate its scientific value. Often the positive and premature statements of a physician relating to new discoveries in medicine are corrected, or at least regretted, at a later date; but sometimes the pride of opinion prevents a retraction in the face of the most conclusive evidence. The result is that such opinions, although they may have been given years ago, are always available to controvert the statements of those who maintain the value of vaccination, of experiments on the lower animals, of the diphtheria antitoxin, etc., and the non-medical public very often accept the opinions which coincide with their preconceived views, or arrive at the conclusion that there is nothing settled in our so-called medical science. It should be our aim to remedy this evil by elevating the standard of medical education, as we are doing in many parts of the country, by impressing upon the rising generation of physicians the importance of laboratory work not only as a means of instruction, but for the purpose of cultivating a scientific spirit of inquiry and just appreciation of the value of experimental evidence; and, finally, by instructing the public with reference to the present status of scientific medicine, the difference between fact and fancy, between the vagaries of the imagination and the demonstrable results of scientific investigation.

With the progress of scientific medicine, we have improved methods of teaching, and it is now generally recognized that reading medical books and listening to lectures is not a sufficient preparation for the practice of medicine, any more than the reading of

books on navigation would be for the responsible position of captain of an ocean steamer. It is for this reason that we insist upon the study of anatomy in the dissecting room, the teaching of methods of diagnosis and treatment at the bedside, and of chemistry, physiology and pathology in the laboratory. It is only within the past few years that our leading medical colleges have provided suitable facilities for practical laboratory work and even at the present day, as I understand, the laboratory courses are not compulsory in some institutions which provide for a four years' course of study as a requisite for receiving the degree of doctor of medicine. From my point of view these laboratory courses are a most essential part of the medical curriculum, not only because the student becomes familiar with the use of instruments and methods which will be of inestimable value to him in the practice of his profession, but especially because of the effect of the kind of training he there receives in enabling him to judge of the imperfections of our unaided senses and the small value of opinions in comparison with that of facts capable of demonstration; as also the relative importance of many things which to the superficial observer might appear to be insignificant and unworthy of attention. He learns not to accept the assertion of the professor in the lecture room or the dictum of any authority if this is in conflict with experimental evidence which he is able to verify for himself. On the other hand, he learns not to have an overweening confidence in his own judgment and powers of observation. He may fail to demonstrate the flagella on the typhoid bacillus, or the presence of the plasmodium in the blood of a malarial fever case, or of a trace of arsenic in the tissues of one who died with symptoms of arsenical poisoning. But having learned by repeated investigation that the failure was due to his want of expert skill in the use of the microscope or in the application of delicate methods of investigation, he learns that it is unscientific and injudicious to give a premature opinion in regard to any subject under investigation, and especially so when this opinion is based upon negative evidence. Failure to find the tubercle bacillus in a given specimen of sputum has little value unless the examination has been repeatedly made by an expert. It unfortunately too often happens that physicians, after a very perfunctory investigation, give a positive opinion based upon negative evidence. I have investigated, I have not found, consequently it does not exist. This is the attitude of the unscientific but self-satisfied man and it often leads to mistakes which are not only discreditable to the individual but damaging to the profession of medicine; for the mistakes of the doctors, as a rule, attract much more attention than their successes. The painstaking work and attention to details required of students engaged in chemical, physiological, bacteriological or histological studies, and the failure in their attempt to repeat an experiment or demonstration if through haste or carelessness they neglect any steps in the necessary technical processes, constitute an invaluable lesson. Indeed the scientific medicine of the present day can only be taught by such methods, and the scientific physician of the future must make his way to fame and fortune by traveling this somewhat difficult and time-consuming road.

I have spoken of the danger of arriving at hasty conclusions upon negative evidence, and wish now to call attention to the fact that physicians too often fail

to recognize the value of negative evidence as opposed to the deductions made from facts coming under their immediate observation. Thus, a case of paralysis following diphtheria may be ascribed to the administration of diphtheria antitoxin, but in view of the fact that paralysis often follows diphtheria when no antitoxin has been given, and of the negative evidence relating to the administration of the antitoxin in thousands of cases and in immunizing doses in other thousands of individuals, the deduction in a particular case that paralysis and the administration of antitoxin stand in the relation of cause and effect may well be doubted. Again, when a case of yellow fever occurs in one of our seaport cities, failure to trace the channel of infection has not infrequently led to the inference that the disease was of local origin. The fallacy here depends upon the assumption that the investigation has excluded all possible avenues for the importation of the infectious material from a foreign source, and a want of appreciation of the negative evidence which shows that yellow fever epidemics never have their origin at interior towns, and that they do not originate at towns on the sea-coast which have no foreign commerce. As well might we conclude, as perhaps some have done, that a case of smallpox is of *de novo* origin because the physician who sought to find the source of contagion was unable to do so. The negative evidence, relating to the non-occurrence of smallpox among persons not exposed directly or indirectly to contagion, is so conclusive that the profession accepts it as a fact that this disease does not originate independently of a previous case. It is a remarkable fact that some physicians still contend that the deaths which occur from hydrophobia in persons treated by Pasteur's method are due to the treatment and not to the bite of a rabid animal. If there is anything definitely settled in medical science we know that there is an infectious disease which we call hydrophobia, or rabies, which is transmitted from one animal to another and from animals to man by inoculation, through the bite of a rabid animal. Yet this well-established fact is denied by certain physicians. And ignoring the fact that more than ninety-nine out of one hundred of those who have been subjected to the Pasteur treatment have not developed hydrophobia although they had been bitten by animals proved in a considerable proportion of the cases to have been rabid the inference is drawn that the few deaths (less than 1 per cent.) from hydrophobia which have occurred during or after the treatment are due to this and not to the bite of the rabid animal which preceded the application for treatment.

My object at present is simply to illustrate the value of negative evidence and not to present in detail the experimental evidence relating to the success of Pasteur's method of preventing the development of the disease in persons bitten by a rabid animal. But I may say, *en passant*, that this is one of the great and well established achievements of scientific medicine, which, however, is still doubted by many physicians not familiar with the evidence and positively denied by those who prepare and circulate sensational anti-vivisection literature. In supporting this view they ignore the evidence and publish the opinions of physicians, more or less distinguished, in opposition to the value of the method; which opinions were in some cases given years ago and before the method had been subjected to a sufficient test to demonstrate its practical value. The point I am trying to make

clear is that it is not only unscientific to give a positive opinion in advance of the evidence, or by one who is not entirely familiar with it, but that such snap judgments reflect discredit upon the profession. They are used by the enemies of scientific medicine to support their denial of any value resulting from animal experimentation, and greatly increase the difficulties of those whose task it is to convince legislative bodies that the progress made in scientific medicine during the past twenty-five years has been largely due to such experiments, and that restrictive legislation would to a great extent, arrest this progress.

Having referred to the injurious consequences of premature and unfounded opinions, especially when given by men of prominence in the profession, I desire to call attention to the best method of counteracting such mischief. This is undoubtedly by united action on the part of the more enlightened members of the profession in behalf of truth and progress. This assistance we have had in combating the antivivisection bill introduced into the United States Senate and vigorously pressed by the members of the Washington Humane Society, supported by their misguided friends in various parts of the country. The result has been eminently satisfactory, and shows that when exercised in a just cause the influence of the medical profession is a factor which will not be ignored even by the Senate of the United States.

Having made frequent reference to scientific medicine, it may be profitable to spend a little time in a consideration of the foundations, methods, resources and prospects of medical science as it exists today. We admit in advance that there is still much in medical teaching which is not science, but which is founded upon unproved theories and the traditions which have come down to us from a pre-scientific age. But medical teachers and writers show a constantly increasing appreciation of the methods of science and of the nature of the evidence demanded by it for the establishment of truth, and a corresponding want of respect for assertions and theories the truth of which has not been demonstrated.

In all departments of science our exact knowledge has been obtained by observation and experiment, and the advancement of science has largely depended upon improvements in methods of observation and experiment. Thus, the primitive astronomer observed the stars with the unaided eye, but the astronomy of the present day depends upon observations made with the telescope, measurements made with instruments of precision and mathematical processes, the results of which can be controlled and proved in various ways. So in medicine, the older physicians relying upon their unaided senses, made and recorded observations, some of which were exact and constitute part of the medical science of the present day, but many of which were inexact and unreliable, as were the inferences drawn from them. Until the compound microscope was invented and perfected we had no means of discerning the micro-organisms which have been proved to be the cause of many of the infectious diseases, or of recognizing the histological changes which result from various disease processes. By the invention and practical application of such aids to diagnosis as the stethoscope, the ophthalmoscope, the clinical thermometer, the laryngoscope, the vaginal and rectal speculum, the stomach tube, the urinary test case, the microscope and the

X-ray apparatus, we are able to recognize pathological conditions which to the unaided senses of our predecessors were beyond discovery, and which being known only by their effects led to vague speculations and vain theories as to the etiology of disease.

Evidently scientific medicine must be founded upon an exact knowledge of the structure (anatomy) and functions (physiology) of the human body in a healthy condition and of the changes in structure and function (pathology) which result from various disease processes; of the causes (etiology), natural history (clinical medicine) and regional distribution (medical geography) of the diseases which afflict mankind and the lower animals (comparative pathology); of the toxic action of various substances from the animal and vegetable kingdom (toxicology), and of the use of these and of other non-toxic substances, physical agents, etc., in the treatment of disease (therapeutics) and of the prevention of disease by disinfection, quarantine protective inoculations, etc. (prophylaxis).

Anatomy, as a fundamental branch of medical science, may be said to have had its birth when dissection of the human body was first practiced by the Greek physicians Herophilus and Erasistratus, about 300 years before the birth of Christ. Since that time constant additions to our knowledge have been made by the same method, and during the present century by the use of the compound microscope, of various staining methods, etc., which have revealed to us the minute anatomy of the tissues. The discovery that various tissues are made up of cells of diversified forms and functions, and that all of these have their origin from one primordial mother cell—the ovum, belongs to the present century and must be regarded as a fundamental fact in its relation to scientific medicine.

The study of structure naturally preceded that of function, and accordingly we find that physiology is of recent birth. Indeed, physiology had no scientific foundation before the discovery of oxygen by Priestly in 1774, and its progress since that time has gone hand in hand with that of chemistry. Some of its most notable achievements during the present century are: The discovery of the digestive ferments and their action, of the function of the red corpuscles of the blood as carriers of oxygen, of the glycogenic function of the liver, of the inhibitory influence of the pneumogastric nerve upon the heart. It is evident that in advance of these discoveries, which all belong to the present century, there was no scientific basis for medicine so far as physiology is concerned. But today the tripod upon which scientific medicine rests, viz., anatomy, chemistry and physiology, is a substantial structure made up of established facts. While scientific medicine could not exist independently of these fundamental branches, they simply constitute the basis upon which the superstructure has been reared, to a large extent during the last half of the present century. The histologic changes which occur as a result of various disease processes, were unknown and unknowable in advance of the invention of the compound microscope, and the same is true as regards the etiology of infectious diseases. While we owe much to the methods of research devised by Pasteur, Koch and other pioneers in this line of investigation, in the application of these methods the compound microscope is absolutely indispensable. And as medicine could not claim to be

scientific so long as we were ignorant as to the etiology of disease, and of the histologic changes resulting from disease processes, we must recognize the perfection of the compound microscope as the most important event of the century from our present point of view. The principle involved in the construction of the compound microscope was invented as long ago as the sixteenth century, but it is only within the present century, and principally during the last half of the century, that those improvements have been made which have made it available for etiologic and histologic studies. There is, however, a growing disposition to suspect that our microscopes, notwithstanding the great degree of perfection attained in their construction, are still inadequate to the task of revealing to us the specific infectious agents of certain diseases, because of their minute size.

In a late number of the *Centralblatt f. Bacteriologie* Löffler and Frosch have published their official report of investigations, made for the German government, relating to the etiology of foot and mouth disease of cattle, the results of which are very interesting in this connection. As in smallpox, rabies, scarlet fever, typhus fever, and certain other infectious diseases, the efforts heretofore made to demonstrate the specific etiologic agent in foot and mouth disease have been unsuccessful. The carefully conducted investigations of Löffler and Frosch also failed to demonstrate the presence of any specific micro-organism in the lymph drawn with proper precautions from the vesicles about the mouth or udder of infected cows. Cultures in various media inoculated with this lymph remained sterile and no micro-organisms could be demonstrated, by the use of the microscope, in stained preparations. Nevertheless, experiments showed that this lymph was infectious material and that calves inoculated with a very small amount of it invariably developed the disease in two or three days. Very much to the surprise of the investigators named, they found that lymph which had been filtered through a porcelain cylinder, which was proved by experiment to arrest the passage of bacteria, retained its full infecting power. That the result was due to the multiplication of the infectious agent in the body of the infected animal, and not merely to the introduction of a very toxic non-living substance present in the lymph, was shown by the small dose required to produce the disease (1-10 to 1-40 c.c. of filtered lymph), and also by the fact that the disease could be transmitted to other animals by inoculating them with like amounts of lymph taken from the vesicles which developed in the calves inoculated with filtered lymph. The authors conclude their report as follows:

It seems difficult to escape the conclusion that the action of filtered lymph does not depend upon a soluble constituent, but upon an agent capable of self-multiplication. This must be so small that it can pass through a filter which retains the smallest known bacteria. The smallest hitherto known bacterium is the influenza bacillus of Pfeiffer. This has a length of 0.5 to 1 μ . If the supposed micro-organism of foot and mouth disease were only $\frac{1}{10}$ or even $\frac{1}{5}$ the size of this, which is not at all impossible, it would, according to the reckoning of Professor Abbe of Jena, be too small to be recognized by our microscopes, even when provided with the best immersion objectives.

In the department of etiology the most brilliant and far-reaching discoveries of the century are the discovery of the anthrax bacillus (1850) and demonstration of its etiologic relation to the disease with which it is associated, by Davaine, Pasteur, Koch and others (1863-1875); the discovery of the tubercle bacillus

by Koch (1882) and the discovery of the malarial parasite by Laveran (1879). These discoveries, so essential to the progress of scientific medicine, would evidently have been impossible without the aid of the compound microscope. But just here I wish to insist upon another point, which is, that for the untrained eye the microscope is little better than a toy and it may even be regarded as a dangerous instrument because of the inevitable mistakes which the novice will make if he undertakes to decide questions of diagnosis by the use of high power oil-immersion objectives without having had the necessary training for such delicate work. In blood examinations, especially, considerable experience is necessary in order to give value to the evidence afforded by a microscopic investigation. It is a very easy thing for the non-expert to overlook the malarial parasite, and still easier to mistake vacuoles in the corpuscles, deformed red corpuscles, etc., for parasitic elements. But the scientific physician will make himself an expert and I trust the time is not far distant when the microscope will be considered by the practicing physician as essential for daily use as is the stethoscope, or even the clinical thermometer.

For the illiterate and even for many of the so-called educated class the whole of medicine consists in the cure of disease by medicines, or by some agency, natural or supernatural, and a failure to cure is evidence that medicine is not a science. We readily admit that the cure of disease is one of the principal objects which medical science has in view, and that from a scientific standpoint therapeutics is very much behind some of the other branches of medicine. This is shown by the diversity of remedies prescribed for certain diseases, and the failure of any one of these remedies to effect a cure in many cases. But on the other hand, therapeutics has made great advances during recent years and by the application of scientific methods of research, the exact value of alleged remedies and of various methods of treatment is now determined with far greater precision than formerly.

A few years ago the intelligent and honest physician did not claim to have any considerable number of specific remedies at his command; but his scientific knowledge relating to the cause, symptoms and pathology of disease enabled him to conduct many cases to a successful termination, which without his assistance would have proved fatal. By the use of instruments of precision and scientific methods of investigation he was able to make an early diagnosis, and to give advice which might stay the progress of a disease, which in its more advanced stages it would have been beyond his skill to arrest.

Recently several additions have been made to the list of specific therapeutic agents, and there is good reason to believe that further discoveries in this direction will be made as a result of investigations now being conducted in pathologic laboratories in various parts of the world. Among the most important recent discoveries in this department of scientific medicine, I may mention the use of thyroid extract for the cure of myxedema, and the antitoxin of diphtheria. The discovery of the diphtheria antitoxin promises to be as important for therapeutics as the discovery of the anthrax bacillus was for etiology, and will no doubt henceforth be regarded as one of the most notable achievements of the century. It resulted directly from laboratory experiments relating to the production of immunity. The demonstration of Pasteur that ani-

mals could be rendered immune against anthrax and other infectious diseases by one or more inoculations, with an attenuated culture of the pathogenic bacillus to which they were due, at once led to an attempt to explain this immunity, and to numerous experimental investigations having this object in view. The result of these investigations was the discovery that the blood of animals rendered immune by such inoculations contains specific antitoxins which may be utilized for the production of immunity in other susceptible animals, and also in certain cases, for the cure of an infectious disease. While the practical results have been most notable in the case of diphtheria, some success has been attained in the specific treatment of tetanus, streptococcus infection, pneumonia, and even in tuberculosis. These results give encouragement to the hope that future investigations may develop methods of obtaining these antitoxic substances in such form and amount as will enable us to successfully use them in the treatment of those infectious diseases for which we have not heretofore had a specific remedy.

A recent discovery of considerable importance from several points of view is the so-called Widal-reaction. This depends upon the fact already demonstrated for several pathogenic bacteria, that during the progress and within certain limits, after the termination of a specific infectious disease due to micro-organism of this class, a substance is formed in the blood which has a specific action upon the particular bacterium which is concerned in the etiology of the disease. The reaction consists in the agglutination of the bacterial cells in groups or masses, and in the arrest of motion in motile bacteria in recent cultures. The diagnostic value of this reaction in typhoid fever is well established, but the reaction is not always obtained during the first days of an attack, when it would be most useful. However, the scientific value of the test is undoubted and it will be of great assistance in determining the true character of atypical cases of the disease, which have heretofore so often been called by some other name. The importance of this reaction for the differentiation of pathogenic bacteria, which can not readily be distinguished by their morphology and cultural characteristics is apparent. Therapeutics has profited greatly, not only by the scientific researches of chemists and bacteriologists, but also by those of the physiologists and physiologic chemists. Investigations relating to the internal secretions of ductless glands have shown the essential rôle which some of these glands play in the animal economy and also the fact that pathologic changes resulting from their impaired functional activity may be relieved by the administration of extracts from corresponding glands taken from the lower animals.

The curative action of thyroid extract in myxedema is well established, and some success appears to have been attained in the treatment of Addison's disease by an extract from the suprarenal bodies. The active substance in the thyroid has been called iodothyron. According to Professor Chittenden, this substance is "a non-proteid cleavage product of a more complex body, naturally present in the gland and characterized by containing both iodine and phosphorus." He considers it pretty thoroughly established that iodothyron "possesses all the peculiarities associated with thyroid therapy."

Abel and Crawford have succeeded in obtaining the active alkaloidal substance from the suprarenal bodies

in the form of a sulphate. This in very small quantities causes a remarkable rise in blood pressure when injected into animals, and applied locally it promptly causes a constriction of the vessels of an inflamed eye.

Let us turn, for a moment, from therapeutics to prophylaxis. Here the progress of medical science has been even more prolific in practical results. Where thousands have been saved by the timely administration of suitable medicines, or by the skilfully performed operation of the surgeon, tens of thousands have been saved by preventive medicine. And preventive medicine is today established upon a strictly scientific foundation. If our practice was *pari passu* with our knowledge, infectious diseases should be almost unknown in civilized countries, and those degenerative changes of vital organs which result from excesses of various kinds would cease to play a leading part in our mortuary statistics. But while our knowledge is still incomplete in some directions, and while individuals and communities constantly fail to act in accordance with the well-established laws of health and the scientific data which furnish the basis of preventive medicine, the saving of life directly traceable to this knowledge is enormous.

Smallpox no longer claims its victims in any considerable numbers except in communities where vaccination is neglected; cholera has been excluded from our country during the last two widespread epidemics in Europe and its ravages have been greatly restricted in all civilized countries into which it has been introduced; the deadly plague of the seventeenth and eighteenth centuries is no longer known in Europe, and the prevalence of typhus (so-called "spotted" or "ship fever") has been greatly limited. Typhoid fever, tuberculosis and diphtheria are still with us and claim numerous victims, but we know the specific cause of each of these diseases; we know where to find the bacteria which cause them and the channels by which they gain access to the human body, and we know how to destroy them by the use of disinfecting agents.

The mortality from tuberculosis is constantly diminishing in our large cities, and the complete destruction of the infectious sputa of those suffering from pulmonary tuberculosis would no doubt go a long way toward the extermination of this fatal disease.

For a long time vaccination as a means of preventing smallpox stood as a solitary example of prophylaxis by inoculation with an attenuated virus. But Pasteur and others following in his footsteps have shown us that protective inoculations may be successfully practiced in several of the infectious diseases of the lower animals. Haffkine's cholera inoculations appear to have been attended with considerable success, and recent experiments in inoculating susceptible persons with cultures of the typhoid bacillus give some encouragement to the belief that they may be rendered immune against typhoid fever by this method. That children may be rendered immune against diphtheria by comparatively small doses of the antitoxin is well established. The value of Pasteur's method of inoculation for the prevention of hydrophobia in persons bitten by rabid animals is now generally recognized by well-informed physicians.

The time at my disposal is entirely inadequate for the purpose of setting forth the present status of scientific medicine, but I trust that enough has been said to justify the claim that we are not "old school doctors," and to show that medicine has not been

behind other branches of science in taking advantage of improved methods of research and in establishing itself upon the sound basis of facts, demonstrated by experiment and observation with instruments of precision.

What has been said will also show that there is no room for creeds and pathies in medicine, any more than in astronomy, geology or botany. Every man is entitled to his own opinion upon any unsettled problem, but if he entertains an opinion in conflict with ascertained facts he simply shows his ignorance. There is no restriction placed upon any physician who graduates from our regular schools as to the mode of treatment he should pursue in any given case. If he sees fit to prescribe a bread pill or a hundredth trituration of *carbo vegetabilis* there is no professional rule of ethics to prevent him from doing so. But if his patient dies from diphtheria because of his failure to administer a proper remedy, or if he recklessly infects a wound with dirty fingers or instruments, or transfers pathogenic streptococci from a case of phlegmonous erysipelas to the interior of the uterus of a puerperal woman, it would appear that the courts should have something to say as to his fitness to practice medicine. There is, however, nothing in the code of ethics which will prevent him from associating with reputable practitioners. But no matter where or when he obtained his medical degree, he can scarcely be said to belong to the modern school of scientific medicine. We must not fail to recognize, however, that the progress of knowledge has been so rapid that it is impossible for the busy practitioner to keep pace with it, and that even the requirement now generally adopted by our leading medical schools, for a four years' course of study, is inadequate for the attainment of such a degree of professional knowledge and practical skill in diagnosis and therapeutics as is desirable for one who intends to practice scientific medicine.

UNIFORMITY THE KEY TO RECIPROCITY.

Presidential Address to the National Confederation of State Medical Examining and Licensing Boards, eighth annual meeting, held at Denver, Colorado, June 6, 1898.

BY WILLIAM WARREN POTTER, M.D.

BUFFALO, N. Y.

The members of this Confederation are entitled to receive the thanks of the communities which they represent upon the substantial progress that is making all over the Union toward a more perfect system of medical education. It is believed that these improvements have been due in a large measure to the influence exercised by State medical examining boards. It has been my privilege on previous occasions when addressing this body to refer to the relationship between the medical schools and the State examining boards, and I hope I may be pardoned for again calling special attention to this subject, which I regard of much importance.

Before entering into its extended discussion, however, let me remark that it is a significant fact that no medical journal or magazine of influence anywhere in the United States has uttered a word of antagonism to the system of separate examination by the State, a practice which is fast becoming prevalent in all the States and Territories. If a few of doubtful standing have endeavored to create dissension, or have expressed opposition to the method, they have found no listeners, or at least they have not been able to impress

their readers with their sincerity or the justice of their wail.

Society papers, too, have been devoid of adverse criticism except, perhaps, in a few unimportant instances. There was a time when considerable criticism was directed toward the character of the examinations, especially at the questions propounded; but as the conditions have been more and more appreciated we observe less complaint of this kind. It has been stated that only teachers in the schools could adequately examine for the State. However much this might appear good in theory, in practice its fallacy has been demonstrated. Only theorists now venture to affirm or reaffirm this now exploded sophism.

No one will, I believe, asseverate that the state examinations are perfect, for there is still much room for improvement; but the work may well be left in the hands of the examiners, who may be intrusted with it with every confidence that they will address themselves to its faithful and honest prosecution.

The colleges have now agreed by a considerable majority that four years is the proper time to set apart to medical training. Not a few are of the opinion that nine months in each year should be devoted to college work. Perhaps all will soon come to this conclusion. The two important questions remaining to be next settled are: 1, uniformity in preliminaries, and 2, equalization of State examination. The first concerns the colleges, the last the examiners must attempt to solve.

By far the most important of the two is the one relating to preliminary qualifications requisite to entitle a neophyte to enter upon the study of medicine. If all medical colleges could agree upon a uniform minimum it would not be long before other moot questions would be settled, even to the interstate indorsement of licenses.

The difficulties in the way are chiefly of degree; for none question, so far as I know, the necessity of some literacy before accepting matriculates. In the East the tendency is toward higher preliminaries than in the West and South. Our Southern friends contend that good doctors can be made with less education than would satisfy our Eastern ideals; that in the mountainous regions not so much of letters as of sense is demanded; that highly educated men will not settle in those districts, hence the people will suffer for want of medical service; and that for these and other reasons not only must they be permitted to accept students with a low grade of educational attainments, but that also they must be allowed to graduate them in medicine after shorter terms of collegiate training. This on its face seems reasonable and is convincing to many; at least it appears to satisfy the consciences of many college professors. It is not an argument, however, that would hold for a moment if all the colleges were endowed. It is difficult to overcome it so long as incomes depend upon numbers in attendance. It has, however, been the experience of schools that have adopted high preliminaries, that the more intelligent students are attracted to their amphitheatres; that a more satisfactory quality of instruction can be imparted; that less time is required in primitive work and that broader training is the result.

It is a mistake to suppose that students will flock to low grade schools. They almost invariably search for the best and will not be satisfied with less. It is

a quality of the American character to surmount obstacles and to triumph over difficulties. This is as true in relation to medicine as in other affairs of life. If medicine is made easily it is not highly prized nor does it command respect. Cheap articles are of little value and are soon wasted. So a professional diploma easily obtained and bestowed upon the illiterate is tossed about or treated with indifference.

It is difficult to understand why there should be opposition to a reasonable elevation of preliminary requirements by any college of pride or standing. Is it unreasonable to say that no candidate should be admitted to matriculate who does not at least possess such acquirements as are demanded of a high school graduate? Surely no experienced teacher could reasonably object to such a standard as a minimum requirement.

Let us see if it works an injustice to the student. I have yet to meet a physician of a few years experience in practice who was deficient in his English education who did not regret the fact. Many have blamed the colleges for accepting them without proper preliminary acquirements. A very large group of this class begin to feel chagrin before their medical training advances very far. They mingle with other students well trained in their preliminaries and are not slow to recognize the immense advantage possessed by such, and to keenly feel their own incompetency. A few, perhaps, are indifferent to such accomplishments, but these generally hire themselves to a medical grocer who deals out his cure-alls by the gallon and advertises a medical staff of attendants with the illusory addendum—consultations free. Or, perhaps they employ a team of horses and a wagon and go about the country auctioneering their wares in sad English and with sadder morals.

Thoughtful men who enter medicine always feel regret when their early education has been neglected and they are quite inclined to blame the colleges for accepting them under such conditions. It would seem, therefore, a kindness to the students themselves to establish such a minimum standard of preliminaries as will make men self-respecting, as well as conduce to an appreciation of the dignity of the profession of medicine.

It seems to me that it has already been clearly demonstrated that neither teachers nor pupils are satisfied with anything less than a reasonable preliminary educational standard. It is true that some college professors are not yet aroused to the real necessities that are presenting on this question; indeed, they in a few instances are inclined to ridicule any attempt to make things better. But such men are more to be pitied than to be condemned. They form the small minority that is constantly growing beautifully less. They sometimes display their oratory in debate or their facile pens in the magazines, but beyond a momentary applause they get very little recognition and still less approbation. I wish all such could have heard Dr. Holland, the distinguished president of the College Association, when he addressed this Confederation last year. It seems to me that his convincing words would have forever silenced opposition to the principles involved in the reforms we are seeking to establish.

In turning to the problem of equalizing or standardizing the State examinations we find a field for serious and ample thought. If we ask the colleges to adopt a uniform standard as to time, four years' courses

of nine months each, and similar methods of instruction in laboratory and clinical work, is it not fair to them that we, ourselves, should establish a similarity of methods in conducting the State examinations? Is it not fair to teachers and candidates for State license that we shall foreshadow the general lines of our examination by a properly prepared syllabus and by modeling our questions upon the modern methods of teaching? Should we not in all the States also have similar examination tests, such as a uniform number of questions in each of the principal divisions of medical science, and a uniform period of time for conducting the examinations? These are some of the questions that are first presented in an inquiry of this kind.

One of the most absorbing questions connected with State examinations is that of reciprocity of licensure. When it is ascertained that physicians licensed by any one State can not commence practice in another State without submitting again to an examination, it naturally provokes criticism against the system. Sometimes this criticism becomes angry and defiant, and examining boards are condemned as being responsible for a faulty system.

Thoughtful men will, however, easily understand how unfair it would be to accept licenses indiscriminately by States having high standards. The pathway to reciprocity consists in establishing not only uniformity of methods of teaching, but similarity in systems of examination by the several States. Just as soon as colleges can agree upon a minimum standard of requirements, the examiners must turn their attention to standardizing their work. I hope much progress will be made this present session of the Confederation in bringing about the former. When this is accomplished it will be in order for a committee to be created by this body, probably to consist of one member from each State and Territory represented in it, whose province shall be to take into consideration the propriety of standardizing the examinations.

It is not my purpose at this time to enter into a discussion of the details of this important subject, but rather to invite attention to it in the expectations that some thought will be bestowed upon it that will lead to a clearer conception of the way and manner it should be dealt with when it comes up for consideration. Some reference was made to it in my annual address last year. I wish to accentuate what I then said on the subject, and to invite your serious attention to this most important and essential duty.

ADDRESS.

Presidential Address delivered before the Arkansas Medical Society,
Little Rock, Ark.

BY A. J. VANCE, M.D.

HARRISON, ARK.

Today treasure-laden memory brings before me as an ever-changing kaleidoscope the faces of the men who have stood as I stand today before this honorable body. Some are still with us giving their energies and intellects to the up-building of our profession. Others have crossed over and are resting from the toil and heat of the day. Not only the faces of the men who have preceded me for the fifteen years I have known this society, but many of their thoughts found an abiding place in my search for medical knowledge, that have often been of great benefit to me.

It is not my object to speak today of the recent developments that have been made in the world of

medical science. It has been a matter of great interest to know something of the foundation of medicine, and in my research I find that it is from the Egyptians that we have our first intimation of the grand science which we represent. They had several divinities who presided over the cure of diseases, the principal one being Isis, a woman. That is supposed to be the author of the oldest medical works. These were engraved on pillars of stone, and afterward collected, formed a part of the so-called Hermetic books, from the prescriptions of which no physician might deviate, unless he was willing to expose himself to punishment in case the patient died. The remains of these books are probably preserved to us in the papyri of Leipzig and Berlin. The Leipzig papyrus was committed to writing in the sixteenth century, B. C. and was the offspring of an epoch of high civilization in Egypt.

The Berlin papyrus was committed to writing in the middle of the fourteenth century B. C., and the substance of both these works are referred back to the fourth millenium before our era.

The papyrus at Leipzig has been only partially deciphered, but in it we find remedies for diseases of the stomach, the abdomen, the bladder, and the removal of glands from the groins, a cure for falling hair, remedies for foul breath, etc. The books are by different titles; for instance, one is called "The Book of Eyes," another, "The Book of the Banishing of Pain." It was the duty of the priests to study these books. We suppose they had specialists, as we read that when an individual needed treatment, he must send to the president of the temple, who selected and despatched the specialist best suited to the case.

It is doubtful if they had hospitals, as it was often the case that the sick were exposed on the street, that they might have the benefit of the advice of the passers-by, who had been cured of a like disease. They did some work in surgery, their process of castration being so dexterous that, even as late as the Roman period, most of the eunuchs were from Egypt. From artificial teeth being found in the mummies, we have reasons to believe that dentistry was also known to them.

History tells us how the original Egyptian medicine began to decline until it finally entirely vanished, except as magic and alchemy. In the middle ages Egyptian medicine was regarded as sorcery.

The next advancement we find in true medicine is among the Greeks in the Ionic school, about six hundred years before Christ. Its founder was Thales of Miletus. After him, for two or three hundred years, there were various theories and schools established, only to go out with probably the death of the originator. It was a time of great superstition and the god Æsculapius held sway over the minds of the masses. Then there appeared Hippocrates, the greatest and most famous physician of all antiquity. He was born 460 years before Christ and was called the great creator of scientific medicine. To him we owe the science of dietetics, as well as prognosis. His feats in surgery were remarkable when it is considered how limited were his instruments. The Hippocrates writings are from fifty to eighty in number, though not all by him, some of them being by unknown physicians of his age and school. He is said to have died 370 years B. C. at Larissa, in Thessaly. Tradition, which throws a halo of glory around all greatness, tells the story that a swarm of bees,

whose honey was especially useful in the treatment of aphthæ in children, made their hive within the walls of his tomb.

After him comes the dogmatic school of medicine, in accordance with Plato. During that time originated the prohibition of drink in feverish diseases, the revival of which not many decennia ago, cost the lives of many fever patients.

The next school of importance was the Alexandrian, and although opposed by other factions it exercised an influence on subsequent antiquity, and even to medieval medicine, its educational merit was felt.

During the next several hundred years we find learning and science mixed more than ever with ignorance and superstition. Men then, as in our day, practiced merely to swindle. An example given us is that of an old and well dressed Arabian, who applied to the president of the college at Bagdad for medical examination. At the first question asked, the man drew forth a well-filled purse and shook out the contents. Though the applicant could neither read nor write, this jingling answer was sufficient and he was given a diploma with the understanding that he should never employ active purges, emetics, or perform venesection.

Through the fortunes of war, as one country would gain prominence, so would her medical theories advance, as the power of the country waned, medicine would deteriorate. But some of the wheat was constantly being gleaned from the chaff and, little by little, the science of medicine gathered strength.

The sixteenth century is of importance, similar to the age of Hippocrates, for during this era, the edifice whose foundation he had laid, was enlarged. The teachings that had gained ascendancy through the dark middle ages were thrown down and the banner of Hippocrates sustained with new and independent thinking, was firmly established. Anatomy received fresh impulse; for years it had been almost obsolete, as the only practical illustration allowed was from the dissection of animals; priests, holding that man being born in the image of God, should not be so mutilated. Surgery and midwifery also received fresh impetus. We find that in this period occurred the re-introduction of that most beneficent operation, podalic version. About that time occurred the first Cæsarean section upon a living woman. It was done by a sow-gelder on his own wife, she being in labor with a number of midwives and physicians in attendance, the child could not be delivered. It is said that he went out alone and prayed, then went back and cut into her as he would one of his sows. The child was delivered, and the woman recovered.

Ophthalmology was likewise newly founded. The revival study of the genuine writings of the ancients brought improvements, historically and philosophically. During this time there were several universities founded in Germany, also in other countries. A man of that period who made himself famous was Ambroise Paré, a Frenchman; originally a barber, he became known as a great surgeon and was attached to the king's court. He is said to have decided to study surgery from witnessing a case of lithotomy. He permanently advanced surgery by improving many old ideas, and advancing new ones that have since borne good fruit. He was the first man to introduce artificial labor at full term in case of hemorrhage.

The seventeenth century is of peculiar interest to the American medical profession, as it witnessed the

foundation and early struggles of what may be called American medicine. The earliest practitioners in the colonies were the medical officers sent out by the emigration companies that established the colonies. Dr. Thomas Wootton accompanied the colony that founded Jamestown, Va., in 1607. In 1608, Dr. Walter Russel accompanied Captain John Smith on exploring tours. However, for some reasons these men did not tarry long, so Dr. John Pot was sent to the struggling little settlement and cast his lot for good or bad among them. He, therefore, enjoyed the honor of being the first permanent resident physician of America. He was a man of merit and to some extent, a leader, as in 1628 he was elected temporary governor of Virginia. Among the "Pilgrim Fathers" who came with their families on the Mayflower and settled at Plymouth, was Dr. Samuel Fuller, the first physician of New England. He was held in the highest esteem, both as a man and a physician. As early as 1629 an effort was made to instruct the youths of this new country in the art of medicine. One Lambert Wilson was employed and sent over with a letter of introduction to Governor Endicott. A part of his duty was to instruct one or more young men in the principles of medicine that they might be helpful to him. In 1647 the General Court published the recommendation, that those studying anatomy might have a malefactor every four years (should there be one) on which to experiment.

At that time London and Paris were the favorite resorts for the Americans who went abroad to pursue their studies, but during the eighteenth century the ascendancy in medicine fell to Germany, where in 1754, was established the first permanent and successful clinical institution. America, though still in its swaddling cloths, was reaching out with increasing vigor and clamor for knowledge, so in 1765 the University of Pennsylvania opened a medical department. During the next sixty-one years there were eleven other schools organized. The Jefferson Medical College in 1826, being the twelfth school organized in America. There are now 151 medical colleges in the United States, six which were established in the year 1893, half as many in one year as in the first sixty years.

As the science advances the necessity of our being fitted to keep abreast of the advancing tide becomes more paramount. The practice of medicine requires a much higher education and more continuous study than is usually demanded in other callings. The grave results for which we are responsible, compel us, if we are true to the cause we espouse, to be constantly seeking at the "fountain of knowledge." It is therefore with pleasure that I speak of the advancements that have been made in our medical schools and laws.

Not many years ago a man who had practiced medicine four or five years without having attended medical lectures, could, by attending one full course of four months, apply for graduation. Soon the five years practice clause was eliminated. Following closely upon that a three years' graded course was adopted, first optional with the student, then compulsory. Now many of our colleges require a four years' course of six, eight or nine months each.

Notwithstanding the requirements for graduation are more severe year by year, and the cost of medical education has more than doubled in the course of ten years, in the principal institutions of the country the

number of students are increasing yearly. Statistics show an attendance in 1894 and 5 of 22,887, with 4827 graduates, an increase of students of 1085 over the preceding year, but a decrease of 306 in graduates.

While the lengthened course of instruction required by most schools may not diminish the number of matriculates, it is no doubt the cause of the decrease of the percentage in medical graduates, and this will probably be still more noticeable as other schools extend their course. A few years ago many of our ambitious graduates in medicine would attend, after graduation, other courses of lectures, taking all the didactic lectures of the course. Seeing the desire of the profession to become more proficient, and recognizing the demand for a college course with all clinical instruction, leaving out the didactic, some of the New York brethren, in the winter of 1880 and '81, organized the New York Polyclinic. This school, together with others since organized, supply a long felt want, enabling a busy physician to get more clinical instruction in six weeks than could be obtained in a five months' course of lectures.

As a result of increased interest and zeal in medical education, there is now some kind of medical practice law in every State and Territory. In twenty-two States, the District of Columbia and the Cherokee Nation, a medical examination is required. In three of these the applicant is only admitted to an examination after showing his diploma. Twenty-five States and Territories and the Choctaw Nation require a diploma. In fourteen of these, the diplomas are required to be from colleges in good standing. Massachusetts honors no diploma except those from colleges in her own borders. Applicants from schools out of the State are required to pass an examination. Arkansas is the only State that grants an examination if the applicant has not a diploma from a college in good standing. In nine States and Territories there are no medical boards, and no one whose duty it is to see that the laws are enforced. It must be that the brilliant achievements of modern medicine and surgery are the direct results of our ever improving system of study and future advancements must depend on the same resources.

The grand march of medical science sweeps ever onward and upward, not in a fitful or fickle way, but with majesty of centuries of study. If we have no ambition to be known outside of our own small sphere it is nevertheless our duty to fit ourselves as well as we possibly can, to render good service to those we are called upon to administer.

We can not all be great in the eyes of the world, but we can prove ourselves faithful to the trusts confided to us. And who has greater trusts than the family physician? He is a part of every family in which he practices. He knows their joys, fears, hopes and disappointments. He is friend and adviser in heights of joy and depths of sorrow. He fosters the feeble life of the wailing mite of humanity as it comes into the world, and the same sympathetic fingers close the eyes of the beloved dead.

Immobilization in Pulmonary Tuberculosis has been tried by Bloch, who reports that a demi-cuirass of plaster on the diseased side stopped the cough, pain and vomiting and reduced the fever, in a number of cases. Auscultation after the removal of the cast in two to three weeks showed that the crepitation and râles had remarkably diminished.—*Semaine Méd.*, May 4.

ORIGINAL ARTICLES.

THE DIFFUSE INFILTRATING FORM OF
CARCINOMA OF THE STOMACH.

Presented to the Chicago Pathological Society, April 11, 1898.

BY LUDVIG HEKTOEN, M.D.

CHICAGO, ILL.

On presenting a specimen of diffuse carcinoma of the stomach to the Johns Hopkins Hospital Medical Society, Professor Welch¹ remarked that there are three diseases that may produce gross alteration in the stomach, indistinguishable from each other to the naked eye, viz., cirrhosis or fibroid thickening of the stomach, primary infiltrating carcinoma and secondary infiltrating carcinoma of the stomach. Orth² regards the majority of instances of contraction of the stomach as due to carcinomatous infiltration, and Welch looks upon a large number of the older cases in literature reported as cirrhosis of the stomach as diffuse carcinoma of this organ, because the diagnoses were not made by microscopic examination.

The first specimen of primary infiltrating carcinoma of the stomach, which I show here, is an example of a fibrous carcinoma, or scirrhus, occurring in a woman 45 years old, who had suffered some months with ascites, which required repeated tapplings; there was also progressive emaciation, but never any prominent gastric symptoms. Postmortem there was emaciation, brown atrophy of the heart and atrophy of the liver. The abdomen contained about 800 cubic centimeters of reddish fluid. The peritoneum was universally rough and thickened and there were firm adhesions between the intestinal coils and the external wall; between the adherent structures cystic accumulations of clear fluid existed, especially about the cecum, around which the structures were matted together in a hopeless tangle. There were adhesions around the spleen, the stomach, and the pelvic organs. The omentum was drawn up into the form of a thick ridge across the upper part of the abdomen. In the mesentery were bands of thick tissue containing small islands of yellow color. There was marked induration and contracted adhesions about the portal vein, the wall of which seemed thick, the lumen reduced. There was no portal thrombosis.

On separating the perigastric adhesions, the stomach was found to be a small mass about one-third the size of the normal organ; it weighs 389 grams. It seems like a solid, hard organ and retains its outline in whatever position it is placed. Its serous surface is rough and shreddy, the serosa thickened, especially along the greater curvature, where the thickening extends into the contracted omentum; the induration and thickening ceases abruptly at the duodenal and esophageal limits.

Palpation does not indicate a hollow organ. An incision along the lesser curvature reveals a small balloon-shaped cavity, the bulb corresponding to the fundus; the cavity would probably hold 150 cubic centimeters. The mucosa is entirely smooth, pinkish, but thrown into huge stiff folds on account of great thickening in the submucosa. The duodenal and esophageal mucous membranes appear normal. The walls of the stomach are greatly thickened, mostly along the larger curvature; here the wall is 1.5 to 2 centimeters thick; the thickening is due to changes

in the submucous and subserous coats principally; these are composed largely of a hard gristly substance. The muscular coat appears more hypertrophied. In no part of the stomach is there any primary tumor. There were no isolated metastases.

Microscopically it is shown that the thickening is due to the growth of a large amount of fibrous tissue in the submucous and subserous coats and to hypertrophy of the muscular layer. Shrunken epithelial cells are present in all coats arranged in small rows and alveolar masses, but the fibrous tissue predominates markedly, and it was necessary to make many sections in order to find any distinct carcinomatous structure. The mucous membrane is not at all characteristic because of a diffuse destruction of its cells and glands. Sections from the omental and peritoneal thickening also show a fibrous carcinomatous structure.

Here we have, then, a diffuse infiltrating fibrous carcinoma of the whole stomach; the growth is primary. The carcinoma has infiltrated the omentum, the peritoneum and the perigastric structures, resulting in great thickening and contracting dense adhesions which, among other results, led to compression of the portal vein and its branches, thus producing an ascites which is of interest from the standpoint of differential clinical diagnosis.

The second specimen of diffuse carcinoma of the stomach concerns an example of the somewhat rare form of infiltrating medullary carcinoma, the ulceration of the mucous surface being confined to a small circumscribed area.

The patient was a man 45 years old, in Dr. Edwards' ward in the Cook County Hospital. The following facts have been abstracted from the clinical notes. The illness began about four months before death with pain in epigastrium, vomiting of food only; has lost almost forty pounds in weight. He was much emaciated, the skin sallow and harsh. There was tenderness over the whole abdomen, the stomach apparently covered by the greatly enlarged liver, which reached below the navel and into the left hypochondrium, being somewhat dome-shaped. Three attempts to secure stomach contents failed; the tube seemed to meet some obstruction at or near the cardiac end of the stomach.

The postmortem showed emaciation and general icterus. There were small but firm nodules on the peritoneum. The lymph glands in the hilum of the liver were much enlarged and caused pressure on the bile ducts, the gall bladder being greatly distended. The retrogastric and retroperitoneal lymph glands were also enlarged and infiltrated. The stomach is very small; it weighs 150 grams; the cavity is very materially reduced in size. On the posterior wall near the esophageal opening is an ulcer with raised margins and rough floor, about 2 by 3 centimeters in extent. Spreading apparently from this point, there has occurred a diffuse infiltration of the walls of the stomach leading to great thickening of all the coats of the organ, which gradually becomes less marked as the pylorus is approached, so that at a point about 6 centimeters from the pylorus the walls seem of normal thickness. The mucous membrane is covered with a grayish black mucus. The liver contained innumerable secondary tumors and weighed 5500 grams.

Microscopically (sections demonstrated) the tumor of the stomach is seen to be made up of rather small

¹ Bulletin Johns Hopkins Hospital, October, 1898.² Pathologische Anatomie.

irregular epithelial cells arranged in a loose stroma in quite solid heaps and columns, which have grown diffusely throughout the coats of the stomach, following apparently the lymph vessels, the infiltration being most pronounced in the submucous and subserous coats, but invading the muscular coat also, in the form of a branching small-alveolated carcinomatous network.

CECAL HERNIA WITH A CLASSIFICATION OF SIXTY-THREE CASES.

BY JOHN H. GIBBON, M.D.

SURGEON OUT-PATIENT DEPARTMENT OF THE PENNSYLVANIA HOSPITAL;
INSTRUCTOR IN SURGERY, PHILADELPHIA POLYCLINIC; SURGICAL
REGISTRAR, PHILADELPHIA HOSPITAL.
PHILADELPHIA, PA.

My attention was turned to the subject of cecal hernia by a case which occurred in the service of Dr. T. S. K. Morton at the Polyclinic Hospital about two years ago and later by another upon which I saw Dr. Richard H. Harte operate at the Pennsylvania Hospital, and it is due to the kindness of these gentlemen and of others who have allowed me the use of their unreported cases, that I am enabled to make the following report. By looking up the literature of this variety of hernia and by making inquiries among operators largely experienced in herniotomy, I have been able to collect and classify sixty-three cases, and from them draw certain conclusions which I trust may prove of interest. In the appended table of cases I have only included the inguinal and femoral varieties of hernia, and of these only such as have been proved clearly to contain some portion of the cecum or appendix, or both.

The history of cecal hernia dates back to the sixteenth century, since when at frequent intervals it has been the subject of much discussion. As to its frequency of occurrence it is rather difficult to speak definitely, but, judging from the number of cases recently reported and the number met with in the experience of single operators, one is led to conclude that the condition is more frequent than is generally supposed. Coley of New York, for instance, reports sixteen cases of hernia of appendix or cecum in 351 operations for femoral and inguinal hernia, and says he has frequently been able to diagnose the presence of the appendix in the sac of herniæ where no operation was done. Another surgeon whose experience is limited to twenty-five or thirty herniotomies has met with the condition four times, but this is unusual, as many men who have had a much larger experience have never had a case. The five cases of Wright of Manchester, which were operated upon and are found in this list, occurred in a series of twenty-four herniotomies done in children.

As to the age at which this form of hernia is most likely to be found, authorities have differed, but it certainly seems that it is in early childhood. Treves has said that it "is practically limited to adults," but Wright, Shepard and others regard it as most frequent in children. It is interesting to observe in this connection that Coley, whose work has largely been among children, has reported sixteen cases of cecal hernia, only one of which was in a patient over fifteen years of age, in 351 operations for femoral and inguinal hernia, while Halsted, in 291 operations for inguinal hernia, had only five cases, and in only two of these was the patient over 15 years of age. Combining these statistics we find that in 642 hernioto-

mies there were twenty-one cases in which cecum or appendix was found in the sac, and of these twenty-one only three occurred in patients over 15 years of age. Of the present sixty-three cases, thirty-three were in patients under 15 years of age, five between 15 and 40 years, seven between 40 and 50 years, and fifteen in patients past 50 years. The oldest patient in this series is that of Dr. W. O. Roberts, a man of 80 years. The frequency of this condition in old age or rather after middle life, as shown in these cases, is probably due to the laxity of the tissues at this time of life.

Sex bears an important interest in consideration of this subject, the condition rarely occurring in women, and particularly is this true of the congenital variety. Only eight of the sixty-three are found in women and these patients are all over 40 years of age, and all are femoral with one exception. The anatomic differences, the infrequency of inguinal hernia in women, and the descent of the testicle in the male accounts for the relative frequency in the two sexes.

The right inguinal is the variety of hernia in which the cecum is most likely to be found, next, the right femoral, then the left inguinal and finally the left femoral. Of the present series forty-four are right inguinal, six right femoral, six left inguinal and one left femoral.

When occurring in adults the condition is most likely to be acquired, while in children it is usually congenital; of the thirty-six acquired cases in the present list only eleven are in children; and of the thirty-three congenital cases all are in children. Of the seven left sided herniæ, three were in children and congenital, and four in adults over 58 years of age and acquired. A great deal has been written regarding the cause of this variety of hernia; in children, the condition, being nearly always congenital, or coming on soon after birth, is more easily explained than in adults where it is acquired. During the process of fetal development the cecum is anchored more or less loosely to the front of the spine by its mesentery, and makes a pretty general circuit of the abdominal cavity before it at last settles down in the right iliac region; and it would seem that during this period it would be most likely to find its way outside the abdominal cavity. Wrisberg has accounted for congenital hernia of the cecum by showing how this portion of the bowel may follow the descent of the testicle in the processus vaginalis. Others contend that in fetal life there is a connecting band between the appendix and cecum and the testicle, and in several of the cases here reported the operator found a band attaching the appendix to the testicle so firmly that division with scissors was necessary before reduction could be made. Macready, who has given this subject a great deal of attention, writes that, "in congenital cecal hernia the peritoneal fold (plica vascularis) is generally still present, together with an unusual amount of unstriped muscle, distributed on the posterior wall of the sac and extending from the testis upward to the cecum." Occasionally the cecum does not become firmly fixed in its normal position and in such instances it has been shown to be of much smaller size than is ordinarily the case; a fact which would render hernia of this gut more likely and would probably account for some of the cases of the acquired variety. Still hernia of the cecum coming on in middle life is not easily explained. I am inclined to think, from several of the histories of patients here reported, that the

Surgeon.	Reference.	Sex and Age.	Variety.	Acquired or congenital.	Contents.	Condition of contents.	Results.	Remarks.
1 Austin, J. E.	N. Y. Med. Rec., 1891, M., 25, 30, p. 622.	M., 25	Right inguinal, strangulated.	Acquired, duration 3 days.	Cecum, appendix and 3 in. of ascending colon.	No sac could be found, cecum adherent to scrotal tissues, pale, appendix free, contents inflamed.	Recovery.	Appendix, 3½ in., removed. Thinks concretion may have escaped with pus without being detected.
2 Annandale, Thos.	London Lancet, 1880, F., 60, 1, p. 627.	F., 60	Right femoral, irreducible.	Acquired, duration 20 years.	Appendix alone.	Pus and blood in and around neck of appendix adherent around neck of sac, occluding it, appendix perforated, but no concretion.	Recovery.	Hernia was never altogether reducible and on day before admission became suddenly larger. Cecum was unintentionally opened. Condition found postmortem; no operation.
3 Bennett, W. H.	Med-Chir. Trans., London, 1890, lxxiii, 129.	M., 52	Right inguinal, strangulated.	Acquired, duration 18 years.	Cecum, containing invaginated ileum without sac.	Below cecum was found a sac containing omentum which was adherent to testicle.	Death.	
4 Black, R. S.	Brit. Med. Jour., 1890, M., 63, 1, p. 1177.	M., 63	Left inguinal, partially reducible.	Acquired, duration 5 years.	Cecum with appendix and portion of ileum.	Appendix adherent to cecum, but not to sac.	Recovery.	Hernia was large.
5 Coley, W. B. (1).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 22	Right inguinal, irreducible.	Not given.	"Cecal."	Not given.	Recovery.	Hernia was large.
6 Coley, W. B. (2).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 4	Left inguinal, irreducible.	Congenital.	"Cecal."	Not given.	Recovery.	Left inguinal hernia also present.
7 Coley, W. B. (3).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 4	Right inguinal, irreducible.	Congenital.	"Cecal."	Not given.	Recovery.	
8 Coley, W. B. (4).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 1	Left inguinal, strangulated.	Congenital.	Cecum and appendix.	Very much congested.	Recovery.	
9 Coley, W. B. (5).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 10	Right inguinal, partially reducible.	Congenital.	"Cecal."	Appendix 4 in. long, and adherent to sac throughout.	Recovery.	Appendix was outlined by palpation before operation.
10 Coley, W. B. (6).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 7	Right inguinal, strangulated.	Congenital.	Cecum and appendix.	Appendix gangrenous and was removed.	Recovery.	Died later from marasmus.
11 Coley, W. B. (7).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 9	Right inguinal, reducible.	Not given.	"Cecal."	Not given.	Recovery.	Large.
12 Coley, W. B. (8).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 9	Right inguinal, reducible.	Congenital.	Cecum.	Not given.	Recovery.	
13 Coley, W. B. (9).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 4	Right inguinal, reducible.	Congenital.	"Cecal."	Not given.	Recovery.	Hernia also present on left side.
14 Coley, W. B. (10).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 8½	Right inguinal, reducible.	Acquired, duration 5 years.	Appendix alone.	Adherent to sac.	Recovery.	Appendix 5½ in.
15 Coley, W. B. (11).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 4	Right inguinal, irreducible.	Relapse after operation by another surgeon.	Cecum.	Cecum adherent everywhere, no sac found.	Recovery.	At first operation cecum was found adherent to testicle, which organ was removed.
16 Coley, W. B. (12).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 6	Right inguinal.	Acquired, duration 2 years.	Appendix alone.	Adherent by mesentery to sac.	Recovery.	Appendix 5 in. long.
17 Coley, W. B. (13).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 7	Left inguinal.	Congenital.	Appendix.	Not adherent.	Recovery.	Appendix 4½ in.
18 Coley, W. B. (14).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 14	Right inguinal, reducible.	Congenital.	Cecum.	Not covered by peritoneum posteriorly.	Recovery.	Hernia was large.
19 Coley, W. B. (15).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 8	Right inguinal, reducible.	Acquired, duration 4 years.	Appendix.	Adherent, removed.	Recovery.	
20 Coley, W. B. (16).	Annals of Surgery, Apr. 1895, Mar. 1897.	M., 9	Right inguinal.	Congenital.	Appendix alone.	Adherent, removed.	Recovery.	
21 Collier, Mayo.	London Lancet, 1890, M., 30, 1, p. 1601.	M., 30	Right inguinal, strangulated.	Not given.	Cecum with appendix and portion of ileum.	Cecum adherent posteriorly.	Recovery.	Very large.
22 Corson, E. S.	Personal com. from Tongue, Burnham.	M., 10	Left inguinal, irreducible.	Congenital.	Cecum and appendix.	Cecum adherent and separated with difficulty.	Recovery.	Appendix was removed; hernia became suddenly larger and strangulated on day of admission.
23 Hart, R. H. (1).	Personal communication.	M., 52	Right inguinal, strangulated.	Acquired, 36 years.	Cecum, appendix and portion of ileum.	Ileum lay in front and was easily reduced; cecum was very adherent, appendix much inflamed, containing concretions.	Recovery.	
24 Hart, R. H. (2).	Personal communication.	M., 1½	Right inguinal.	Acquired.	Cecum and appendix.	Cecum adherent to sac.	Recovery.	Hernia very loose; appendix not removed.
25 Halsted, W. S.	Personal communication (1).	M., 8	Inguinal, reducible.	Acquired shortly after birth.	Cecum and appendix.	Appendix adherent to sac.	Recovery.	Large hernia.
26 Halsted, W. S.	Personal communication (2).	M., 3	Inguinal, indirect, strangulated.	Congenital.	Cecum, appendix and ileum.	Ileum adherent to sac.	Recovery.	Large hernia; appendix removed.
27 Halsted, W. S.	Personal communication (3).	M., 13, 4	Inguinal, reducible.	Congenital.	Cecum and appendix.	No adhesions to sac.	Recovery.	
28 Halsted, W. S.	Personal communication (4).	M., 48	Inguinal.	Acquired; duration since childhood.	Cecum and appendix.	No adhesions, part of sac formed by meso-ecum.	Recovery.	Very large hernia.
29 Halsted, W. S.	Personal communication (5).	M., 35	Inguinal, strangulated.	Acquired; duration 6 hours.	Cecum, appendix and 3 in. of ileum.	Appendix injured by trauma, which produced hernia.	Recovery.	Appendix removed.
30 Keetley, C. B.	Med. Press and Circ., 1890, 1, p. 85.	F., 53	Right femoral, irreducible.	Acquired; duration 6 months.	Appendix alone, somewhat swollen.	No distinct peritoneal sac.	Recovery.	Appendix removed; a portion of hernia reduced before operation.
31 Knowles, J. H.	Boston M. & S. Jour., 1890, cxxiv, p. 215.	M., 8, 12	Right inguinal, strangulated.	Acquired; duration 8 months.	Cecum, appendix and small gut.	Contents congested; "stinking pus" in sac.	Recovery.	No perforation of appendix, not removed.
32 Le Conte, R. G.	Personal communication (1).	M., 41	Right inguinal, strangulated.	Acquired; duration 32 years.	Large portion of small intestine and appendix.	Appendix adherent at internal ring.	Death.	Adhesions very dense. Dr. LeConte thinks portion of bladder was present in sac.
33 Le Conte, R. G.	Personal communication (2).	M., 41	Right inguinal, strangulated.	Acquired; operated on 22 years ago.	Cecum, appendix and small intestine.	Appendix adherent at internal ring.	Recovery.	
34 Le Conte, R. G.	Personal communication (3).	M., 54	Right inguinal, partially reducible.	Acquired; duration 35 years.	Cecum, appendix and small intestine.	Almost universally adherent to sac.	Death.	

35	Le Conte, R. G.	(Persons) communica- tion (4).	Right inguinal, reduc- ible.	Acquired; duration 12 years.	Cecum, appendix and small intestine.	Recovery.	Hernia also on left side, but right was much larger.
36	Morton, T. S. K.	(Persons) communica- tion.	Right inguinal, stran- gulated.	Congenital.	Lower part of sac con- tained ileum, upper part cecum.	Recovery.	
37	Paget, Stephen (1)	London Lancet, 1891, M., 1, p. 928.	Right inguinal, stran- gulated.	Congenital.	Cecum and a very large appendix.	Recovery.	
38	Paget, Stephen (2)	London Lancet, 1891, M., 1, p. 928.	Right inguinal, stran- gulated.	Congenital.	Cecum, appendix and small intestine.	Recovery.	
39	Paget, Stephen (3)	London Lancet, 1891, M., 1, p. 928.	Right inguinal, stran- gulated.	Congenital.	Cecum, appendix and small intestine.	Recovery.	
40	Rand, H. W.	Brooklyn Med. Jour., 1893, VII, p. 751.	Right femoral, stran- gulated.	Acquired.	Cecum, 6 inches of colon and small intestine.	Death.	Perforation of peritoneum, sac filled with feces; artificial anus made. No concretions.
41	Roberts, W. O. (1)	Med. Age, Detroit, 1896, vol. XIV.	Left inguinal, stran- gulated.	Acquired; duration many years.	Cecum and appendix.	Recovery.	
42	Roberts, W. O. (2)	Med. Age, Detroit, 1896, vol. XIV.	Right inguinal, stran- gulated.	Acquired.	Cecum and large part of ileum.	Recovery.	
43	Roberts, W. O. (3)	Med. Age, Detroit, 1896, Vol. XIV.	Right inguinal, stran- gulated.	Congenital.	Cecum and appendix with pin protruding from appendix.	Recovery.	Pin protruded from posterior wall of appendix which was removed.
44	Roberts, W. O.	Med. Age, Detroit, 1896, Vol. XIV.	Right inguinal, stran- gulated.	Acquired.	Cecum and appendix.	Recovery.	
45	Roberts, John B.	Annals of Surgery, M., 1895, 25, p. 611.	Right inguinal, stran- gulated.	Acquired, duration many years.	Cecum with absence of appendix.	Recovery.	Very large hernia, two operations previously.
46	Shepard, F. J. (1)	Annals of Surgery, M., 1892, 12, p. 122.	Right inguinal, stran- gulated.	Acquired, duration 11 years.	At upper part of sac a mass of omentum and cecum, latter covered only in front with peri- toneum.		Thinks this was a double hernia, became suddenly larger 2 years ago, before which time was reduc- ible.
47	Shepard, F. J. (2)	Annals of Surgery, M., 1892, 12, p. 122.	Right inguinal, irre- ducible.	Acquired, duration 9½ years.	Cecum.	Recovery.	
48	Silcock, A. O.	British Medical Jour., Nov. 1888, 1, p. 294.	Right inguinal, stran- gulated.	Congenital.	Cecum and appendix.	Recovery.	Large hernia.
49	Stevens, W. H.	Alabama Medical and Surgical Age, 1893, 4, VI, p. 521.	Right inguinal, stran- gulated.	Acquired.	Appendix alone, gan- greous, sac filled with pus.	Recovery.	Hernia on left side also.
50	Treves, Frederick	British Medical Jour., Nov. 1887, 1, p. 382.	Right inguinal.	Acquired, duration 6 years.	Two sacs with common neck; outer contained cecum, appendix and portion of colon and ileum; inner contained ileum.		Hernia large.
51	Freves, Frederick	British Medical Jour., Nov. 1887, 1, p. 382.	Right femoral, reduc- ible.	Acquired, duration 2 years.	Cecum and appendix.		Cecum and appendix easily pal- pated.
52	Van Hook, W.	Medical and Surgical Reporter, 1896, 74, p. 313.	Right inguinal, stran- gulated.	Acquired, duration 1½ years.	Sac contained large amount of jelly-like amber-colored fluid.		Proved to be a cyst of appendix, which was ruptured in reduction.
53	Walker, John B.	Medical Record, 1897, LI, p. 227.	Right femoral, stran- gulated.	Acquired, duration 29 years.	Cecum, appendix and ileum.	Recovery.	Constriction divided but yet not reduced for several days on ac- count of its congested condition. Operated upon twice previously, same contents.
54	Wright, G. A. (1)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal, stran- gulated.	Acquired, duration 12 months.	Cecum, appendix and portion of ileum.	Recovery.	
55	Wright, G. A. (2)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal, reduc- ible.	Congenital.	Cecum, appendix and ileum.	Recovery.	Also has umbilical hernia.
56	Wright, G. A. (3)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal.	Acquired, duration 1 week.	Cecum, appendix and ileum.	Recovery.	Large hernia.
57	Wright, G. A. (4)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal, reduc- ible.	Acquired, when 8 months old.	Cecum, appendix and ileum.	Recovery.	Also has umbilical hernia.
58	Wright, G. A. (5)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal, reduc- ible.	Acquired, duration 2 weeks.	Appendix plainly pal- pated.	Recovery.	Hernia on left side also; contents reducible except appendix, which could be plainly palpated.
59	Wright, G. A. (6)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal.	Congenital.	Cecum, appendix and omentum.	Recovery.	All symptoms of obstruction were here present.
60	Wright, G. A. (7)	British Medical Jour., Nov. 1887, 1, p. 506.	Right inguinal.	Congenital.	Appendix plainly felt before operation.	Recovery.	Patient's two brothers were rup- tured.
61	Waring, H. J. (1)	St. Barth. Hos. Rep., 1891, xxvii, p. 180.	Right femoral, stran- gulated.	Acquired, duration 12 years.	Appendix alone.	Recovery.	Dr. DaCosta thinks this hernia was congenital.
62	Waring, H. J. (2)	St. Barth. Hos. Rep., 1891, xxvii, p. 180.	Left femoral, incar- cerated.	Acquired, duration 24 years.	Cecum, appendix and portion of ileum.		
63	DaCosta, J. (Chal- mers)	Personal Communica- tion.	Right inguinal, incar- cerated.	Acquired (?) when 17 years old.	Cecum, appendix, por- tion of colon and ileum with a very large mass of omentum.	Recovery.	

cecum has been dragged down by a pre-existing hernia of the ileum. Given a small cecum, and perhaps one freely movable, and a hernia of the ileum it would seem plausible that some additional muscular effort might produce a hernia of the large gut. Dr. Harte's second case would rather show the reverse of this argument, however, as here the hernia of the cecum undoubtedly ante-dated that of the small bowel, which lay near the internal ring and was easily reduced while the cecum was below and firmly adherent. In several instances the appendix has been found just within the internal ring while the rest of the sac was filled with coils of the ileum; one of Dr. Le Conte's cases illustrates this condition.

Regarding the mobility of the cecum, Treves, by an examination of 100 bodies, has shown it to be very great; in many instances he could make it touch the liver and frequently was able to carry it to any part of the left pelvis. The various positions in which the appendix has been found would tend to confirm this opinion. The question regarding the sac of cecal hernia is interesting; Mr. Treves has done much to convince the profession that the old teaching of absence of sac in these cases is wrong. The idea of complete or partial absence of peritoneal covering in cecal hernia has been traced to Scarpa and it was until recently the prevalent belief. In his examination of 100 bodies Treves found the average distance from the tip of the cecum to the reflection of the peritoneum from the posterior wall of the colon to be four inches. In a very few of the cases here tabulated the sac was deficient posteriorly, but in nearly all there was a complete sac.

Probably the most interesting part of this subject is the condition in which the contents of a cecal hernia are found. In the present list twenty-eight were strangulated, twelve reducible, eleven irreducible, ten not stated, and two incarcerated. It will be observed in looking over these cases that beside the tendency to strangulation the adhesions between the contents and to the sac are more frequent in this variety of hernia than in other kinds. I was surprised not to find a greater proportion of diseased appendices in this condition. Bajardi found the appendix diseased in 30 per cent, which is much larger than is here presented although there will be found in this list several cases of very far advanced disease of the appendix. One of the most interesting cases is that of Dr. Stevens of Cardiff, Ala., in which the sac was filled with pus and the sole occupant a broken-down appendix, which was adherent all round its base to the neck of the sac, thus protecting the peritoneal cavity. Dr. Rand of Brooklyn, reports another case of perforated appendix and pus in the sac. A unique case is the one of Dr. W. O. Roberts of Louisville, in which he found the cecum and appendix in the sac and a pin protruding from the posterior wall of the appendix. A specimen in Guy's Hospital Museum also shows a pin protruding from an appendix which was present in the sac of a hernia. Dr. Van Hook reports the very unusual condition of a cyst of the appendix, ruptured in reduction and the sac filled with cyst contents. Annandale's case is very much like that of Dr. Stevens. He found pus and blood in and around the sac, the appendix being adherent within the neck. It will be observed that inflammation of the appendix has occurred in those instances in which it was alone in the sac, Dr. Rand's case being the only exception. There are several instances in this

series where hernia was present on both sides, but, probably the most interesting case of this kind is reported by Broca, who found in the right sac, a loop of the colon, and in the left, the sigmoid flexure, cecum and several inches of ascending colon, and ileum. The presence of concretions and foreign bodies in the appendix are rare in this list of cases, again making a contrast with Bajardi's series. He studied ninety-eight cases and found the appendix inflamed in thirty, containing foreign bodies in eleven, perforated in sixteen, and gangrenous in four. In comparatively few of the present cases was the appendix diseased; its condition is frequently not stated and the supposition is that in these instances it was healthy. Foreign bodies were present in two cases and perforation occurred in five. Before leaving the pathology of cecal hernia two of the cases in this series should be mentioned. One is that of Dr. Bennett of London, who found the cecum to contain a portion of invaginated ileum. The other is one of congenital absence of appendix, reported by Dr. John B. Roberts.

The diagnosis of cecal hernia is very seldom made before the sac is opened, except, perhaps, in children and in old people, where the wall is very thin and permits of palpation of the appendix. Coley has been able to make the diagnosis on several occasions in children, and he and others have been able to reduce all the contents of a hernia except the appendix, which was adherent and could be easily outlined. Several of the cases here tabulated were diagnosed before operation. In nearly all the cases where the cecum was in the sac, the hernia is described as large, and when the appendix alone was present there was usually pain and tenderness.

The treatment of this variety of hernia varies little from that applied to hernia generally, unless in cases where a diagnosis is made, and then I think an early operation should be the rule, because of the tendency to strangulation and disease of the appendix. Particularly is this true where the appendix alone can be felt in the sac and is painful and tender on palpation, because here suppuration is more likely to occur than where other portions of intestine accompany it. The removal of the appendix will depend upon its condition and the attitude of the individual operator toward the general question of its removal.

Of the sixty-three cases here appended thirteen have never before been reported and of the others I have endeavored to avoid any that might be included in other classifications.

CONSERVATIVE SURGERY.

Presented in the Fourth Annual Meeting of the American Academy of Railway Surgeons at Chicago, Ill., Oct. 6-8, 1897.

BY RICARDO ORTEGA, M.D.

CHIEF SURGEON MEXICAN INTERNATIONAL RAILWAY,
DIAZ, MEXICO.

The large number of maimed persons I have seen among railway employes, prompts me to make a few remarks with a view to enlisting co-operation in preventing the unnecessary mutilation of the injured.

It is true that we frequently encounter ungrateful patients who blame us because the member we have saved, after toiling with it more than we would have been obliged to do had we resorted to amputation, is not in as good condition as it was before the acci-

dent. Others aver that we are not surgeons if we do not mutilate. This opinion, however, is of no importance when we are conscious of having done our best. It is the better plan to preserve all we can of an injured organism, even at the risk of retaining, for a time at least, that which may ultimately be an encumbrance. I have had cases when it seemed that to preserve an injured member would be useless or a nuisance to the patient. Nevertheless I have, as an almost invariable rule, suggested preservation and results have more than fulfilled my hopes.

Among others, I remember the case of J. Griffin, a locomotive engineer, who had his left elbow crushed. The wound showed a comminuted, compound fracture of the upper epiphysis of the radius and cubit, and lower part of the humerus. Splinters of bone showed through and were extracted from the skin. My colleagues proposed amputation, but I succeeded in having it deferred until it should become absolutely necessary. Such necessity never occurred, for with proper antiseptic treatment, and infrequent, dry dressings the arm was saved, and, later on, the patient became known as one of the most efficient engineers on the road.

In my thesis on soliciting admission to the National Academy of Medicine of Mexico, I referred to the case of an articular gunshot wound. The larger portion of the bullet lodged in the tibio-astragaloid articulation, and the smaller fraction in the soft parts in front of the same articulation. The wound was infected by pieces of sock driven in by the bullet. Yet, at the proper time I extracted the bullet and the patient entirely recovered the use of his feet. I could cite many other cases of similar nature, but I think it will be sufficient to state, that since the year 1888, when I entered the service of the Mexican International Railroad, the only amputations I have been obliged to make have been one forearm at the lower third, one foot at the metatarsus and two fingers.

There is nothing so easy as to thoroughly clean a wound and the surrounding skin. In the case of train and shop men, it is often unnecessary for the washing process to be extra thorough if the skin has been stained with lubricating oil, because, although I have had no opportunity to make a bacteriologic examination of that substance, it is my impression that it has aseptic qualities, since in nine years practice I have yet to detect a case of poisoning from contact with black oil. Possibly its aseptic qualities are due to its having been subjected for a long time, to heat caused by friction in the machinery. The washing I have mentioned, can be followed by hemostatic treatment, and then cover the bloody surface and fill in the interstices with an antiseptic salve, such as iodoform or salol 5 grams, antipyrin and borate of soda, each 1 gram, and vaselin 30 grams. This has an advantage over powdered iodoform, in that it prevents the gauze and cotton, which complete the dressing, from adhering to the wound, and causing, on their removal, not only considerable pain to the patient, but also tearing of soft tissues and consequent delay in healing.

A crushed member can be kept dressed in this manner for fifteen days or more, if no indications appear that the dressing should be removed. This seldom happens, because the flaps, which may become affected with gangrene, are surrounded by an antiseptic salve which prevents their infecting other parts of the wound. Many of these diseased flaps, which we considered impossible to preserve, surprise us, not

only by living, but adhering properly, if we have correctly placed them. Then we may not have to intervene, and if we are obliged to do so, we will find the patient in a better condition, and no longer under the influence of the shock. Before wrapping up the member, we have to remove its extremity if it is only held by a few tendons or a flap of skin or muscle insufficient for nutrition. If we find a stump with a tendency to assume a conical shape we will have to trim it, but all this can be done without risk.

Dr. Paul Reclus, in an able article on the subject, published last year in the *Revue de Chirurgie*, advises the use of bichlorid of mercury and carbolic acid, in small quantities, in addition to the antiseptic salve, and the insertion of gauze in all the spaces. This last suggestion appears very appropriate in cases of large crushed wounds. He ends by saying, "henceforth we shall have no traumatic amputations."

In preserving instead of amputating an injured member, we do a more humane duty, and accomplish a practical purpose. We save the company we work for from payment of a heavy indemnity.

A PLAN TO MODIFY THE JAPANESE JINRIKISHA INTO A WHEELED LITTER FOR REMOVING THE WOUNDED IN BATTLE.

BY EDMUND ANDREWS, M.D.

LATE SURGEON OF FIRST REGIMENT, ILLINOIS LIGHT ARTILLERY.
CHICAGO, ILL.

Twenty-eight years ago a great industrial revolution occurred in Japan. It was nothing less than a total change in the ancient vehicles employed in the transportation of passengers. Wheeled carriages had seldom or never been used before this. A few officials rode on horseback. The usual plan was for the poor to go on foot and the rich to hire coolies who carried them litter-fashion in sedan chairs and cagos. The cago was a kind of litter suspended to a pole and carried on the shoulders of two coolies. As this is very exhausting labor each coolie carried also a stick as long as from his shoulder to the ground. When they found it necessary to rest they set these sticks upright under the ends of the pole, thus relieving them from the weight. Men of means traveling to a distant destination hired four or six coolies, who relieved each other from time to time. This laborious mode of travel went on for ages. In 1870, twenty-eight years ago, an ingenious man in the city of Tokio discovered the fact that coolies can draw about six times as much weight on a pair of light wheels as they can carry in a cago, besides traveling at twice the speed. This was an astounding discovery in Japan, and the author of it forthwith invented the famous vehicle called the jinrikisha. *Jin* means man, *riki* is power and *sha* is a carriage, literally the man-power-carriage. The Americans in Japan jocosely call it the "Pull-man-car."

It is simply a small chaise with light wheels about forty inches in diameter and drawn by shafts, between which a coolie stations himself instead of a horse. Seizing the shafts he trots off from four to six miles an hour. A fair ordinary day's work is a little less than twenty miles, but in emergencies they will do more. Two of them have been known to take a passenger forty miles in a day. The jinrikisha men are short and very strong and their business develops tremendous muscles in their thighs and in the calves

of their legs. Two of them will trundle a passenger up a high hill without difficulty.

The new invention won a phenomenal success in Japan and drove the old cagos totally out of existence. There are now in the city of Tokio alone over ten thousand jinrikishas.

It seems strange at first glance that European and American armies should still use hand litters exclusively in lugging the wounded from the line of battle back to the ambulances, but there are reasons for it. Up to almost the present time old-fashioned muskets were used, that had only a short range, and the danger belt behind the fighting line was so narrow that the ambulances could be driven up pretty close, enabling the litter bearers easily to bring the wounded to them. The new long-range guns have immensely widened the danger belt, and in level open ground the ambulances and the field hospitals will have to be kept very far back. Now the carrying of wounded men on hand litters is a very severe and exhausting work. Lieut. von Kries of the Austrian army experimented to see how much could be accomplished by the bearers. He found that eight litters carried by thirty-two men (four bearers to a litter as usual) got back only thirty-two wounded to a distance of about four hundred yards in three hours, and they were giving out with exhaustion at the end. Now the ambulances must often be twice that distance away, and in a severe action the bearers would not be able to clear the field.

Now if the jinrikisha idea were modified so as to give us a light pair of wheels with a slender frame, on which an ordinary removable hand litter could be laid with the wounded man upon it, two bearers could trundle the patient back to the ambulances in a very short time with little fatigue. Like hand-litter bearers, they must lie down when the gusts of heavy firing come and get up and move on in the lulls between them. These lulls in the firing will come with the new weapons fully as often as they did with the old ones, thus permitting the removal of the injured to go rapidly on.

This idea is not altogether new. Mr. John Furley, a surgeon in England, devised a wheeled litter a number of years ago. Also Gen. C. H. Thompson of the United States Army planned another, which was quite ingenious but rather complicated. As the short-range guns were still in use the wheeled litters were not urgently needed and so the idea was dropped. A United States officer explains that the fighting of the American troops at that time was exclusively against the Indians, and carried on in such an extremely rough and broken country that General Thompson's wheeled litter could not be made available.

To some extent this obstacle of rough country will exist hereafter, as it has in the past, but the great armies of the future will often line up for battle across broad open plains where ambulances can not come near the front, and then wheeled litters will become very necessary assistants in clearing the field of the wounded.

For valuable information on Oriental vehicles I am indebted to a Japanese gentleman, Prof. Massuo Ikuta, of the University of Chicago.

3912 Lake Avenue.

THE ANCIENT AND MODERN INSTRUMENTS USED IN DIAGNOSIS AND TREATMENT OF DISEASES OF THE ESOPHAGUS AND STOMACH.

Read before the Colorado State Medical Society, June 15, 1897.

BY C. D. SPIVAK, M.D.

ASSOCIATE PROFESSOR OF ANATOMY AND LECTURER ON DISEASES OF THE STOMACH AND INTESTINES, DENVER UNIVERSITY, MEDICAL DEPARTMENT.
DENVER, COLO.

The stomach and esophagus remained a terra incognita with reference to the diseases they are subject to as long as these organs remained inaccessible to direct examination and the application of local remedial measures. The invention of an instrument that possesses both diagnostic and therapeutic virtues has thrown much light into these obscure regions of the human anatomy. The instrument which now supplies the want felt for centuries is the stomach tube. This insignificant looking piece of rubber tubing, which has found a place in the armamentarium of every modern physician, was not born in a day. Like every other instrument, the stomach tube has a history.

History of the stomach tube.—The origin of the stomach tube is shrouded in mystery. Who was the first to dare insert an instrument into the esophagus and down into the stomach for some definite purpose we do not know. Was it necessity or curiosity, was it the juggler or the magician who first practiced this art, is equally unknown; it is reasonable to suppose that it was necessity, the mother of invention. We find in *Æsop's* fables a story wherein the crane is supposed to have used his long beak for the purpose of extracting a bone which stuck in the throat of the fox. Under similar circumstances, man may have used his fingers, or has improvised an instrument to extract a foreign body from his own or his fellow's throat. While performing this primitive operation he may have noticed that irritating the esophagus produces vomiting.

The first mention of a contrivance which may be considered as the forerunner of the stomach tube is to be found in the "Scholia" of Aristophanes.¹ The highly cultured Greeks, in cases of poisoning, introduced a feather into the esophagus and thus produced vomiting. The Alexandrian Meander tells us that the physicians of that period used to produce emesis either by hand, feather or wooden stick.

The Romans went a step farther. Their ideal was to eat well. It seems that they had only one meal a day—from morning till bedtime. In order to escape the evil consequences of an overloaded stomach the last course of every menu was a *vomitivum*. The emetic, however, proved at times a troublesome luxury. The dose was too small and an annoying nausea was the result; or the dose was too large and vomiting had no end. They had to give up the vomitum in disgust, and the noble Romans resorted to their noble fingers as a sure cure for the oncoming dyspepsia. Running the finger down the throat was in most cases sufficient. Some Roman genius invented the *pinna*,² made of a bundle of goose-quills which was besmeared with iris oil. The throat was irritated with the pinna until vomiting ensued. Claudius, history tells us, used to have his throat tickled with the pinna by his physician after each meal. He was thus tickled to death by the order of his wife

Cure of Asthma with Serum Treatment. Two cases are reported of complete cure of asthma accompanying streptococcus rhinitis, with injections of antistreptococcus serum. This experience confirms Landouzy's assertions that asthma is caused by a toxin, usually tuberculous.—*Presse Méd.*, May 4.

Agrippina; instead of the iris oil the pinna was dipped in poison.

In the "Collecta Medicinalia" of Oribasius,³ a celebrated historian of ancient medicine in the fourth century, we find an exhaustive description of the various methods used to produce vomiting. For instance, the candidate for emesis was laid upon a kind of a hammock which was swung and shaken until an artificial sea-sickness was brought on. The finger comes next in order, the pinna is also mentioned, and a new instrument *digital vomitorium* is introduced. This consisted of a leather glove finger, about ten to thirteen inches long, the lower two thirds of which were stuffed with woolen fiber, while the upper third was empty to receive the directing finger of the physician. Before using, the digital vomitorium was lubricated with the oils. The last named instrument can truly be considered as the primitive stomach tube or stomach sound, judging by its length and mode of introduction. For the tube is based on the same principle as the sound—a contrivance to substitute for, or lengthen, the finger of the operator where the region to be explored is inaccessible.

With the fall of the Roman Empire, gormandism was at an end, and all the methods used to produce emesis were, little by little, forgotten. The noble Romans were glad enough to take food and have it stay on the stomach. The various emetics were used only by medical men in cases of *indicalo morbi* or *indicalo vitalis*.

Avicenna,⁴ in the eleventh century, mentions an instrument *gomor*, made of silk and used in cases of poisoning, "et gomorem in os ejus mittat et ipsum cum instrumento vomere faciat." Mercurialis,⁵ who flourished in the sixteenth century, mentions, in his book on poisoning, among other things, *lorum vomitorium*, an instrument known from antiquity, and vaguely described by Scribonius Largus,⁶ as far back as the first century. It is supposed by Leube to have been a leather strap treated with nauseating substances, which produced emesis by its nauseating taste, when introduced into the esophagus.

All the above described contrivances had one object in view, viz., to facilitate the evacuation of the stomach contents. Another step toward the perfection of the sound was effected when surgeons attempted to apply it to the extraction of foreign bodies from the esophagus. Both the material and form of the instrument underwent some modification. It was constructed of metal, and the tubular form was for the first time introduced. Arculanus,⁷ in 1557, used a short tube made of lead with numerous holes to catch the foreign body when introduced into the esophagus. Ryff⁸ (1559) and Scultetus⁹ (1679) used a silver tube. Hildanus¹⁰ (1641) was known as an expert in removing foreign bodies from the esophagus by means of a bent silver tube, to the end of which was attached a piece of sponge the size of a hazelnut.

Hieronimus Fabricius ab Aquapendente¹¹ (1716) made further advance in the development of the sound. In cases where the foreign body could not be extracted from above, he advocated the procedure of pushing the same further down into the stomach by means of a bougie. He used for this purpose a long wax candle, the size of the little finger, which he bent somewhat and introduced into the esophagus.

At the threshold of the new era, the end of the seventeenth and the beginning of the eighteenth century, we find the stomach tube performing a new

office, that of direct treatment of the mucous membrane of the stomach. This procedure, which has gained universal adoption only during the last few decades, was known to and practiced by the aboriginal tribes of America. Daper,¹² in 1673, in his ethnographic studies of the South American inhabitants, gives the following account of the treatment of the stomach as practiced by the Tapugas, a Brazilian tribe. "They have a wonderful way of cleansing their belly from the inside. They stick a rope of platted sharp leaves down their throats until it reaches the stomach, and there they turn and twist it so long until they vomit and spit blood. Hereafter they draw the rope and the belly is cleansed."

About the same time that Dapper published his description of the Tapugas, an instrument became known in Europe which served the same purpose. Judging by the number of monographs¹³ written about it, the instrument must have created quite a sensation. The instrument was known under various names—stomach cleaner, stomach scratcher, and stomach brush.

According to Socrates¹⁴ (1713), ab Aquapendente had improvised a stomach sound for the purpose of cleaning the stomach, and some kind of a stomach cleaner was known and secretly used by the fraters of the Italian monasteries. Rumaseus,¹⁵ in 1659, published a pamphlet entitled "Organum salutis," or "an instrument to cleanse the stomach." It was patented by the inventor and was sold extensively in London. His stomach brush was made of a smooth, flexible whalebone from two to three feet long, the lower end of which had a knob-like projection to which a tuft or tassel of silk, cord, or linen was tied. "Those suffering from an excess of mucus in the stomach should introduce the brush and remove the same."

At about the same time the stomach brush was used in France, Norway and Germany. Sorbier¹⁶ tells of a Provencal who used to push into his stomach a stick of ash-wood three feet long, the lower end of which was in the form of a spoon, and therewith he cleansed his stomach. Pechlin¹⁷ relates that two Norwegian peasants exhibited the trick before the court of Denmark in the presence of the king.

Leube¹⁸ gives an interesting account of a German ambassador to Russia, who returned from the Moscovite debauches with his stomach completely ruined. He was sent, by the king, to one of the monasteries for treatment. He found the inmates all in robust health. One frater was 115 years old and yet he was able to read and write without the use of spectacles. This gave him courage to undergo the mysterious treatment. He was obliged to donate a large sum of money to the monastery and give an oath not to reveal the arcanum as long as he lived. This arcanum was nothing but a stomach-brush. He was given a goodly dose of brandy, and ordered to lie quiet for a quarter of an hour. Two fraters introduced the brush. He spat, vomited, implored and cursed, but the holy fathers went on with their work of scrubbing the stomach; volens nolens he had to take a large quantity of water and the brush was once more introduced. This time large quantities of mucus, bile, blood, and offensive pus were brought up. After partaking of some chicken broth and an elixir he soon fell asleep. The operation was repeated four times. It was then noticed that the food brought up with the brush was completely digested, with the exception of a few pieces of turkey. The fraters reasoned that there

must be some mucus still left in the stomach, and he had to undergo the ordeal once more. In eight days he was completely cured, and left the institution. For fourteen years he used the brush himself and kept the secret. But to use his own words, "Out of Christian pity to the many sick and afflicted and the consumptive who have lost all hope of recovery" he broke his vow, and stomach brushes were manufactured in Leipzig and elsewhere by the thousands and sold as a cure for all sorts of sicknesses.

Socrates¹⁹ asserted the stomach brush to be a panacea against all ailments emanating from the stomach, and even as a makrobiotic for all who wish to prolong their days upon the earth. "Brushing out the stomach, with an elixir of saffron, aloes, and myrrh administered after, protects the body from poisons and pests; brings a good memory, improves the eyesight, etc., improves cold and hot fevers, asthma, mammary abscess, consumption, cephalalgia, apoplexy, toothache, croup, etc." It seems, the author remarks, as if death has laid aside his scythe and taken a stomach brush in his hands.

We possess a drawing of the instrument as given in the writings of Socrates and Heister. It is twenty-four inches long, made of a strong, carefully tempered, double brass rod, covered with plaited silk. At the lower end is attached a round brush of horse hair or goat's beard, which resembles the brushes now used for cleaning lamp chimneys. The *modus operandi* was very simple. The patient was given a little brandy and a pint of water. The brush was dipped in water and then introduced.

The citizens of Breslau were at one time stomach-brush struck. Thus Kundmann²⁰ writes in 1737: "There was no beer company at which some did not apply it to themselves after drinking heavily, either the same night or on the following morning, after having snored out their intoxication through the open mouth, if they were distressed with thick phlegm in the throat." "But," the author continues, "since those who have used the tube suffered either from nausea or continuous vomiting, some had hemorrhages, and others could not walk upright afterward, a good many became asthmatic, and a few gave up the ghost, the credit of the tube fell just as speedily as it rose."

I have dwelt at some length upon the history of the stomach brush, because its form, application and the enthusiasm with which it was received, by both the profession and the laity of 200 years ago, must be considered as an important landmark in the history of therapeutics. In an epoch when physicians were almost helpless in the treatment of internal diseases, and when, at best, they had a confusion of pharmaceutical agents whose actions were unintelligible to them at such an epoch, an internal organ was for the first time subjected to local surgical treatment, in spite of the conservative objections of the savants of the day.

Leube in his book "Die Magensonde,"¹⁸ to which we owe most of our information about the stomach brush, concludes his article as follows: "Nobody will wonder nowadays were the stomach brush to appear in a new and revised edition, and add to our instrumentarium for the treatment of diseases of the stomach. On the contrary I hold it quite worthy of a trial to apply some such instrument, as a therapeutic agent, in cases of neurosis and atony of the stomach."

The prophecy of this great seer of gastrology, uttered some twenty years ago, has come to pass. At

the International Medical Congress, held at Rome, in 1894, Dr. Fenton B. Turck²¹ of Chicago, presented an instrument which he called *gyromele*, and which is nothing else than the stomach-scratcher of two centuries ago, dressed up in the *fin de siècle* style.

The *gyromele* consists of a flexible cable to the end of which is attached a sponge covering a spiral spring which can be removed and changed. The cable passes through a rubber tube, and this again is attached to a revolving apparatus for the purpose of producing revolutions of the sponge within the stomach. The *gyromele* is used for diagnostic and therapeutic purposes. As the evolutions of the *gyromele* can be readily palpated on the abdominal wall, it is therefore obvious that the size and position of the stomach can be ascertained. It was found by the inventor that the revolutions of the *gyromele* stimulate the secretion of the gastric juice and, therefore, it can be used as a means of differential diagnosis between functional disturbances and atrophy of the stomach. The adherent material can be removed from the *gyromele* and subjected to a microscopic, chemic and bacteriologic examination. It can be used as a therapeutic agent in cases of functional anacidity, in mucous gastritis, where simple lavage is not sufficient to remove the mucus adherent to the wall of the stomach, and in cases of neurosis.

To return to the old stomach brush, as might be expected it has fallen into disrepute; physicians have only used it now and then for therapeutic and diagnostic purposes. Thus, Nahuys (1784)²¹ reports a case of a neoplasm in the esophagus where the brush was used so as to cause an inflammation and discharge of pus from the neoplasm by the hard friction of the instrument. In the celebrated case of Willis (1673)²² the patient, suffering from paralysis of the esophagus, used for sixteen years to push the food down with a modified brush; it was made of whalebone at the end of which a piece of sponge was tied. Jobus Basterus (1677),²³ in a case supposed to have been "excrecentia glandulave in œsophago indurato" made the diagnosis by means of the sound, and proved that the esophagus was permeable. Valisnery (1733),²⁴ used the sound as a dilator in a case of stricture of the esophagus. Van Geuns (1767),²⁵ in a case of stenosis of the cardia, used a sound with an ivory tip of an oval shape—an instrument used to this day. Abercrombie (1820),²⁶ used a silver wire, to the end of which was attached an egg-shaped knob, in a case of stricture of the esophagus in which bougies were of no avail.

In cases of impaired deglutition, the question naturally arose how to introduce food or medicine into the stomach. To meet this indication the instrument must assume the form of a tube, the lower end reaching the stomach.

Hieronimus Capivaceus (1598),²⁹ was the first to recommend artificial feeding in cases of impaired deglutition "*canulam intra gulam immittendam*," which canula was provided with a bulb holding nourishing fluid. By compressing the bulb, its contents was driven through the tube into the stomach.

Fabricius ab Aquapendente³⁰ was the first to publish a comprehensive account of artificial feeding in cases of lockjaw. He introduced food through the nose by means of a silver bent tube, the lower end reaching above the epiglottis. In order to prevent the fluid getting into the larynx, the lower end of the tube was bent a little forward so that the contents would first

run into the mouth and thence by the act of deglutition, be swallowed. Later, he recommended the passage of the tube around the posterior molar teeth.

The next modification that the stomach tube underwent was with reference to its size and the material of which it was manufactured. It became obvious that the tube must be long enough to reach the stomach and must be made of flexible material. The latter requirement was met by the ingenious Van Helmont (1646),³¹ who taught how to make catheters from leather. To make a stomach tube it was only necessary to make the catheter a little longer. John Hunter, the father of English surgery, in a lecture delivered before the Royal Society of Sciences, May 20, 1771,³² advocated among other things the injection into the stomach, through hollow bougies or catheters, such irritating substances as ammonia, turpentine, etc.

The idea of using a hollow sound with a bulb-syringe attachment for the purpose of injecting fluid into the stomach once being firmly established, it was but a natural consequence that the same apparatus, by reversing the valves, should be applied in cases where the withdrawing of the stomach contents is indicated, *i. e.*, as a pump.

The English surgeon F. Bush,³³ was the first to use the stomach tube as a pump in cases of opium poisoning. He injected water into the stomach by means of the bulb, and then by reversing the valves he evacuated the thus diluted poison. One of the earliest descriptions of the so-called stomach pump was given by Dr. Samuel Moore.³⁴ The credit of the perfected stomach pump as it is used at present belongs to an American, Dr. Wynau³⁵ of Boston. The elder Bowditch³⁶ was the first to use it for the evacuation of empyematous collections.

In the second decade of this century various stomach pumps were described, invented, and used by Jukes,³⁷ Ward,³⁸ Reed,³⁹ Weiss,⁴⁰ and others. The sounds used in all the apparatus were made of elastic rubber, two and one-half feet long, and one-fourth of an inch in diameter, at the end of which a perforated ivory ball was attached (Jukes), also the same tubes with their ends rounded off, having two openings at the sides (Read and Weiss). Lafarg's⁴¹ esophagus tube had three openings, one at the end and two at the sides.

A RECORD OF THE DISEASES OF FIVE HUNDRED AND SIXTY CONVICTS UNDER-GOING CELL CONFINEMENT.

BY M. V. BALL, M.D.

EX-PHYSICIAN TO THE PENITENTIARY FOR THE EASTERN DISTRICT OF PENNSYLVANIA.
WARREN, PA.

In this paper I have attempted to catalogue the more serious ailments affecting a number of convicts, whom I have had the opportunity to examine on admission and to have under observation for a period of from one to three years. I have excluded those already confined when I entered on my duties and all those who were admitted in the last year of my service, whom I had not sufficient time to observe.

In order to show the effect of confinement, if any, I have divided the whole number into two groups. In Group 1 are convicts under observation for an average term of eighteen months. In Group 2, convicts under observation for an average term of two and one-half years. In the latter group will be found many more of the malefactors who had committed crimes against the person or who belonged to the habitual offenders. There were 260 in Group 1 and 300 in group 2.

It will be noted in Table 1 that three of the thirteen deaths occurred within the first year of confinement, four within the second year and six within the third year; when this is computed on the number undergoing confinement the difference will be found more marked, since there were 560 who served at least one year, while only 300 served more than two years. The rate in the first year is therefore 0.53 per 100, while in the third year it is 2 per 100, or nearly four times as many.

Tuberculosis.—Of those who had phthisis on entrance only one died. Of those who on account of marked family history together with an enfeebled physical structure would be inclined to contract phthisis, only one became decidedly phthisical, and one developed scrofula.

Tuberculosis is usually very prevalent in prisons and yet only four of the deaths were from this cause among a population containing seventeen affected on entrance. Of the nine persons apparently contracting the disease during confinement, three died, showing a special virulence. Colored convicts when attacked succumb very speedily. Under proper quarantine for the sick and extra attention to those who are inclined to become affected the mortality from this disease has been lessened in a number of prisons.

Scrofula.—There were eight cases on entrance and

HISTORY OF INSANE AND INSANE TENDENCY.

No.	Age.	Nationality.	Crime.	Family History.	Personal History.	During Confinement.	Termination.
150		Italian.	Assault with intent to kill.	Negative.	Depression on head from accident. Is melancholic.	Attempted suicide twice, without success; improved.	Behaved well after; discharged at expiration of sentence.
285		American.	Assault with intent to kill.	Negative.	Was an inmate of insane asylum four years before. Has delusions; was commanded by God to assault a stranger.	Delusions continue.	Remanded to insane asylum on expiration of sentence.
861		German.	Vagrancy.	Negative.	Apoplexy three years before, causing dementia. Has loud cardiac murmur. Does not understand reason for arrest.	Slightly improved.	Discharged on expiration of sentence.
434		American.	Assault on his mother.	Insanity in father and sister. In sister phthisis.	Very intemperate, illusions at times; quarrelsome when drunk; twice in prison for assault on mother.	No signs of mental disturbance.	Discharged.
519		American.	Larceny.	Negative.	Is phthisically inclined; has given parents much trouble.	Shortly after admission complained of poison in food; refused to eat; became very debilitated.	Was given in charge of parents in fairly good condition; returned in a few weeks on another charge; delusions absent.
626		American.	Larceny.	Negative.	Given to excess in drink and venery. Served four terms in prison for assault and larceny. No symptoms of insanity on admission.	One year after admission delusions of persecution arose which persisted to the end of sentence.	Was discharged not cured.
731		American.	Assault and battery.	Bastard.	Intemperance and venery. Seven times convicted for assault and battery. On last sentence developed dangerous delusions and had to be placed in cell by himself. Hallucinations of hearing and delusions of persecution. Has only been discharged two weeks.	Fairly well behaved, but inclined to be bothersome if angered.	Still in prison.
839		Negro.	Burglary.	Insanity in father. Phthisis in grandparents.	Excess in drink and venery; has had syphilis; served 4 times in prison within 4 years; believes he is persecuted by officers; talks to himself and is easily angered.	Served his sentence without any further trouble.	Discharged.
964		American.	Assaulting officer. Received 7 years for resisting arrest, while stealing some brass to perfect an invention.	Father and aunts insane.	Was hit on the head four years ago with a heavy weight, causing fracture of skull; since then occasional spells of loss of memory; escaped from insane asylum shortly before. Is very emotional, k. j. greatly exaggerated, cries frequently, mind worried, no sleep.	Under nourishment and hyoseyamus great improvement. Is a good machinist; given work at trade; has considerable inventive genius.	Still in prison. Case was considered by lunacy commission as fit for asylum, but advised remaining in prison until the end of sentence.
1030		American.	Murder. Killed officer while serving term for murder.	Negative.	Symptoms of insanity during confinement: hallucinations and delirium; killed keeper who attempted to quiet him; is ugly and will not speak to anyone; is quiet now without any known delusions.	Remained reticent during the whole three years of my service. No hallucinations; would not speak to me; would eat and sleep regularly.	Transferred to insane asylum, where he was killed the next day in some unknown manner.
1127		Italian.	Assault with intent to kill.	Unknown.	Has been arrested four times for assault; claims to be the victim of persecution; had delusions and noisy delirium in county prison; apparently sane on entrance.	Shortly after admission claimed relation with King of Italy, protested against being confined; was very noisy at times, singing and shouting; delusions of grandeur persisted after delirium wore off.	Still in confinement.
1219		American.	Murder. Shot a police officer while resisting arrest.	Persecution. Insanity in mother.	Syphilis two years before; otherwise healthy.	Two years after admission had delusions of persecution and hallucinations, not marked.	Still in confinement.
1328		Irish.	Assault with intent to kill.	Negative.	Had been acting strangely for several years; irritable; was sane on admission.	Shortly before discharge 2½ yrs. after admission, commenced to refuse food; claimed it was poisoned; became emaciated; under treatment he improved.	Discharged apparently well; few days after asked me to have him placed in an asylum; he was afraid of himself; this was done.
1427		American.	Larceny.	Drink in father. Mental trouble in some of family.	Seven times arrested for drunkenness; has been a tramp for four years.	Delusions of persecution six months after entrance.	Discharged on expiration of sentence.
1533		Irish.	Murder. Killed a man while drunk.	Negative.	During childhood had fracture of skull, leaving depression.	Suicidal thought, so that he would not commit any more crime; 1½ yrs. later debilitated and an attack of hemoptysis.	Still in prison.
1654		German.	Malpractice. Abortionist.	Negative.	Well on entrance.	An attack of acute delirium, on the second day of which he killed himself by hanging.	Death.
1758		American.	Murder. Killed a friend in a quarrel.	Phthisis in mother and sister.	Had syphilis and was intemperate; in army had skull fractured which caused a dementia for one year; drink causes delirium quickly; k. j. greatly exaggerated; pin-hole pupils; is very excitable at times.	Had no symptoms during confinement.	Discharged well after three years' sentence.
1827		French.	Assault with intent to kill. While in a fit of jealousy shot a woman.	Negative.	Had spinal meningitis eight years before; is hysterical and hypochondriac; imagined he could not walk; after the deed he shot himself in the jaw, causing a fracture.	Behaved well after a short time. Was made cook and performed his duties fairly well, but when suffering with the least pain made much ado over it.	Still in confinement.
1922		Colored.	Murder. While drunk.	Insanity in father and cousin. Phthisis in mother.	Given to drink and venery; does not know anything about the crime; is very ignorant and dull witted; inclined to phthisis.	One month after, scrofula developed and it was allowed to form a large axillary abscess, which was opened; phthisis then developed and death followed one year after admission.	Death.
2021		Colored.	Arson. Fifteen years' sentence.	Unknown.	Set fire to barn to see the hay burn, then summoned help; does not know what fifteen years mean; microcephalic; is an imbecile.	Gave no trouble during two and one-half years.	Still in prison.

eight arising during confinement. Those in whom the disease developed usually gave a history of a previous attack or had suffered from syphilis; nine of the sixteen cases were negroes; in five phthisis was present in the parents and five had syphilis in recent years. In only four was there no evidence of disease in the

family or in their own lives. Cod liver oil was found very efficacious in the treatment of the enlarged glands.

Organic heart disease.—This seemed to be quite common among the convicts, but whether more so than among adults generally I am unable to say. In 2800 convicts examined by my successor and myself,

organic disease was detected in 3.2 per cent. In the causes of death of 790 convicts, occurring in the penitentiary during 65 years, 5 per cent. are attributed to disease of the heart. In our list, twenty were affected, making 3.5 per cent.; only one of this number died; the majority presented no subjective symptoms and were unaware of the existence of any defect.

TABLE 1.—DEATHS. GROUP 1.

Cause.	Time served, years.	Condition on entrance.	Diseases during confinement.
Cerebral tumor.	1 1/2	Scrofula and Syphilis	Pneumonia, purpura rheumatica (died in Philadelphia hospital after an operation on brain).
Typhoid	1 3	Good.	None.
Typhoid	1 1/2	Good.	None.

GROUP 2.

Tuberc. pulmon.	3 1/2	Good.	Pneumonia.
Tuberc. pulmon.	1 7/12	Good.	None.
Tuberc. pulmon.	9/12	Good.	Intestinal tuberculosis.
Tuberc. pulmon.	11/12	Tuberculosis pulmonalis and imbecility.	Scrofular abscesses.
Sarcoma of thigh.	2	Sarcoma of heel.	Leg amputated.
Epithelioma of tongue.	2 1/2	Good.	Tumor grew gradually for two years.
Carcinoma of cervix.	2 7/12	Good.	Noticed only 7 months before death.
Typhoid fever.	2 1/6	Scrofula and syphilis	None.
Aortic insufficiency.	2	Organic heart lesion, loss of compensation.	Under treatment constantly.
Suicide, hanging.	1 1/2	Good.	Acute delirium.

NOTE.—All three cases of malignant growths died after the expiration of sentence, but in so short a time that it is but fair to include them in this list.

TABLE 2.—Diseases on admission of 560 convicts.

Diseases.	Group 1.	Group 2.
Phthisis.	8	9
Phthisical history in family and tendency thereto	9	6
Valvular heart disease	13	7
Scrofula.	4	4
Syphilis (secondary)	4	3
Insanity.	4	5
Insane history and tendency thereto	2	3
Locomotor ataxia	1	1
Renal ascites	1	1
Chancroid	5	2
Gonorrhea	9	2
Bronchial asthma	2	3
Pregnancy	1	1
Sarcoma	1	1
General debility	5	3
Hystero epilepsy	1	2
Imbecility	1	3
Simulated insanity	1	2
Opium habitue	1	2
Apparently healthy	190	240

TABLE 3.—Serious diseases developing under confinement, in those apparently healthy on entrance.

Diseases.	Group 1.	Group 2.
Phthisis	4	5
Scrofula	4	3
Insanity	2	3
Syphilis	1	2
Typhoid fever	4	2
Acute pneumonia	1	1
Carcinoma of uterus	1	1
Epithelioma of tongue	1	1
Abscess	1	1
Debility	1	2
Apoplexy (two attacks)	1	1
Acute rheumatism	1	1

Syphilis.—Here we have recorded only such cases as manifested the disease in an active state. There were many who gave a history of having suffered from the disease in years gone by, but seemed free from all symptoms at the time of examination. Many had suffered from gonorrhea and other venereal diseases at the time of their arrest, but had been cured in the county prisons before reaching the penitentiary. This probably accounts for the fact that I have never observed a case of delirium tremens or any great discomfort from the withdrawal of alcohol in prison, in persons who were chronic drunkards outside.

I have only attempted to note the more serious illnesses here. There were numerous demands upon the physician for treatment for intestinal trouble and bronchial affections such as ordinary diarrheas and colds.

The insane element has ever been an interesting topic and especially in this particular prison, where the method of confinement has been wrongfully accused of causing the insanity. I have dealt with this subject elsewhere to which those interested are referred.¹ I have however noted here, somewhat in detail, the kind of individuals received and the character of the insanity.

In this paper I have drawn no conclusions; it is simply a contribution of facts to the study of convicts, hoping that others might be stimulated to furnish statistics relating to the health of different groups of individuals observed for a like period of time. The ordinary reports of prisons and asylums relate to a constantly fluctuating population. Here I have tried to show the condition of the individual on admission, and the serious diseases he has been subject to during a certain time, and again I have grouped a number of individuals together all serving the same length of time and compared them with another group serving a different length of time. True, these statistics relate to convicts undergoing a particular method of imprisonment and can not, therefore, be applied to convicts in general without further study. If a similar statement could be had from Auburn or Sing Sing prison some comparison as to the effect of the two methods, cell and congregate, on the health of convicts might be made.

TUBERCULOSIS; ITS SEED, ITS SOIL AND ITS TREATMENT BY MEDICAL ASEPSIS.

BY T. J. MCGILLICUDDY, M.D.

NEW YORK CITY

In the consideration of this subject we will endeavor to simplify it as much as possible, giving it a novel presentation so that its general conception may become clearer and more easy of comprehension. There is no special advantage in clothing and often obscuring our ideas in ultra scientific verbiage. Common sense is what we want in medicine as elsewhere, and the practical aspect of the healing art must not be lost sight of and forgotten in the fogs of hair-splitting laboratory work. Micro-organisms are but a part of medical science, but they have of late engrossed our attention to the exclusion of other and important factors in the production of disease.

In all the long history of that eternal war which man is waging more or less successfully against disease and its consequences, no phase of the conflict is of such vital importance to so many individuals as that which relates to the diseased condition of the human body, generally known as tuberculosis. Great epidemics of cholera, yellow fever, the plague, or the black death, from time to time, overshadow it in interest and public attention, but when we consider that, notwithstanding these more conspicuous causes, it is to tuberculosis alone that one-fifth of all the deaths upon this planet is said to be due—that in the United

¹ "Insanity Among Convicts;" Journal of American Medical Association, Vol. xxi, No. 13, Medical Reports of Eastern State Penitentiary for 1892-93-94. "Tuberculosis in Prisons;" Proceedings of National Prison Association for 1894.

States it is estimated there are nearly five hundred fatal cases every twenty-four hours, we may in some degree realize how much more we have to dread from this insidious and ever active foe of the human race than from those the possible mention of which as possibly approaching our shores is the signal for wild alarm.

The subject is also specially interesting because of the very remarkable revolution that has taken place in the ideas entertained by medical men as to its cause and treatment—a revolution modern in its origin, and by no means ended. Less than a generation ago, tuberculosis was believed to be hereditary, and in such cases not to be prevented; it was thought to be contagious; it was practically regarded and treated as incurable. Today the best medical opinion does not consider it hereditary, nor contagious, that is, from personal contact, like smallpox or measles, nor incurable. It is infectious under certain conditions.

There is no doubt but that it can be prevented, even where there is a hereditary weakness which predisposes to the disease; there is positive proof that it can be, and is daily being cured, except in advanced stages.

In the treatment of tuberculosis and in the light of modern theories, the truth of which, since the discovery of Koch, announced in 1882, no longer remains to be demonstrated, two things are to be considered: 1, its seed; 2, its soil. Without seed there is no crop. Thanks to the spirit of modern investigation and research, the seed of tuberculosis has been defined and described until there is no more doubt as to its nature and characteristics than there is about a grain of wheat. Without entering into the unprofitable and probably unanswerable problem of where this seed first originated, bacteria or germs generally are coeval with the first appearance of organic life on the earth. It is now believed to have no breeding place in nature outside of men and animals, and their secretions. Developed in the lungs of a tuberculous patient, discharged in the sputum that comes so freely from the affected source, the tubercle bacilli go forth upon their mission in numbers beyond the conception of mathematics to compute. It is estimated that 5,000,000,000 may be contained in a single drop of water. So long as moisture is maintained they can not escape, but when dried without exposure to the sun they will retain their pernicious and virulent activity for months, and are easily set in motion—each one a living thing. Freezing does not effect them; the gastric juice does not kill them, and burial in the earth does not destroy their vitality.

When we consider the number of individuals who are more or less affected with this disease, that they are to be found in all classes of society and all parts of the world, that they are coming and going in public conveyances, and frequenting public places, that they are expectorating right and left, and that each deposit contains millions of bacilli, waiting to be taken up on the wings of the wind and carried wherever air permeates, we can realize the hopelessness of escaping their all but omnipresence. And yet we see boards of health acting under advice of those who surely have not given the subject all the study it deserves, suggesting well-intended but pitifully inadequate methods to exterminate the bacilli, by passing ordinances against public spitting without doubt a beneficial measure—and some have even gone so far as to recommend the compulsory isolation of all persons

affected—a plan that would be cruel in many cases, if it were generally practicable, which it certainly is not. Every movement in the interest of purer air should certainly be encouraged, and public cleanliness should be made imperative, but if the eradication of tuberculosis depends entirely upon the enforcement of such measures, we shall wait a long time before it will become as rare as leprosy is now in the United States. The seed of tuberculosis does not always sprout where it falls; if the tubercle bacillus attacked everyone exposed to its influence, the race would have been exterminated ere this.

Not only seed, but soil, is essential for the crop. As in agriculture, so in pathology, the right seed is no more essential to a crop than is the proper soil. You may sow wheat in Broadway every day for 100 years, and wait as much longer for a harvest. The germ is there; under the proper environment of earth and moisture and protection, it will sprout and grow, but lacking these, it comes to naught. Just so with the bacillus. If the soil for it is fertile, it will do its deadly work: if sterile, it will just as surely fail. In the sterilization of the soil into which the tubercle bacillus enters, rather than in seeking to escape its presence altogether, lies the hope of the consumptive.

How shall this be effected?

Life is much the same no matter where we find it. In biology, a sharp line of demarkation, separating animal from vegetable life can not well be drawn. The physiology of man and of plants are much alike, in many ways almost identical. The same causes operate to produce disease and death in both. The bacillus is not the primal factor, but is always secondary to the malnutrition and uncleanness. The earth makes the sap, and the sap makes the plant—the food makes the blood, and the blood makes the body. If the earth ceases to nourish the plant, away at the top the leaves begin to wither and die; if the food ceases to nourish the body, the lungs, which are to man what the leaves are to the plant, begin to fail. Just as it is the yellow, sickly leaf that is attacked by germs, which upon the green and vigorous growth have no effect, so it is in the weak unnourished and impoverished lung, that the tubercle bacillus finds the soil it needs. The tubercle bacillus is therefore one of the bacilli of decline and decay.

Tuberculosis is not a disease of the lungs alone, although it is in the lungs that the decline of the system often makes itself most prominently manifest; it is in the lungs, or other parts affected, that the bacilli, acting under the great and beneficent law of nature, which thus provides for the disintegration and return to dust of that which has passed its usefulness and lost its vitality, begin and carry on their mission. As this disintegration progresses, the soil becomes more and more fertile, and there is more of it. Unless this decline can be stayed, unless the diseased and decaying tissues can be cleansed and vitalized, or sterilized, and fitted to withstand the ravages of the rapidly increasing germs, there is positively no hope for the patient. To check the deterioration is the first step in the restoration to health.

What course of treatment is then indicated?

The answer is simple, as truth is always simple. Purify and strengthen the system.

It is a fundamental principle of surgery and external medicine that nothing is so conducive to the healing of external wounds and diseases as perfect cleanliness. If the lungs are to be cleansed and if internal

surfaces are to be healed, why not adopt what is in effect a similar treatment? The natural sluiceways of the body furnish the channels; the eliminatives provided by the skillful physician furnish the means not only of cleansing the stomach and the digestive tract generally, preparing it for better and more effective work, but filtering through the whole system these best of remedial agents find their way eventually to the kidneys, bowels and pores of the skin, which, carefully kept open by the ingestion of hot water in sufficient quantity, warm baths, massage and gentle systematic muscular exercise, eliminate the disease wherever it is possible.

Equally important is it to strengthen the system by the careful selection and use of foods. There is truth underlying the saying that, "if you take care of the stomach, the lungs will take care of themselves," and in the building up of the body it is imperative that the digestive organs should be in a normal and healthful condition, and be stimulated to increased activity by proper strengthening exercise systematically carried out under medical direction. We see the value of this method in the training of the athlete, or even the race horse. The physiologic law that exercise strengthens, and that all development is of gradual growth, must be considered in connection with the fact that about all the body, except the frame-work, the padding and the nervous mechanism is muscle, and most of the organs, including the lungs, functionate only through muscular activity. Therefore, the great importance of strengthening the voluntary and involuntary muscles by exercise and proper diet and regimen is apparent. This must not be lost sight of in the treatment.

By internal cleanliness, blood-washing and by elimination, we cleanse the tissues; by improving the nutrition, we increase the germicidal power of the blood and the vitality of the body. The presence of fermenting or festering materials within the body is the cause of many of the symptoms we call disease. The removal of them by the eliminatives is medical asepsis. This may not be always easy to accomplish, but this is the direction in which our efforts should be applied, and this is a method that should be used in the treatment of many diseases of bacteriologic origin. In the treatment of surgical diseases, what would we think of a man who did not believe in surgical asepsis, that great principle which holds good in all surgery. In medicine, which can not in treatment be separated from surgery, each one treats pneumonia, typhoid fever, scarlatina, phthisis, etc., according to his own ideas and without any great underlying principle of medical asepsis. It is simply a case of do as you think best or do nothing, the so-called expectant plan of treatment, and the results are correspondingly various.

Medicine and non-operative surgery, as is now well understood, have no sharp line of separation. The same principles in treatment, I claim, hold good for both. The more we can simplify these and thus make them easily understood, the better it will be for the medical profession and their patients.

Many plants in their sap, or blood, as we might term it, have a material that is noxious to low forms of life. We see this in their products, belonging to the carbolic acid series, the salicin from the willow bark, quinin from cinchona bark, etc. And so it is with the sap or blood of the healthy animal body. Would not this principle, in a measure, account also

for the efficacy of the serum or antitoxin treatment? The fresh serum, like that of Maragliano, containing the germicidal principles of healthy blood is poisonous to the germ life developing in the exhausted, devitalized tissues of the patient.

MALARIA.

BY R. S. MICHEL, M.D.

PROFESSOR OF INTERNAL MEDICINE, CHICAGO CLINICAL SCHOOL; MEMBER OF STAFF WEST SIDE HOSPITAL. CHICAGO, ILL.

It is said that one-seventh of the human race perishes of tuberculosis—a fearful mortality—but thanks to modern investigation, this enormous death-rate will be greatly reduced. Of even greater importance to humanity is malaria. It stands as an insurmountable barrier to the occupancy and civilization of a large part of the globe. Immense countries, fertile in soil and rich in countless natural products, otherwise capable of supporting a dense population, are lost to the aggregate wealth of the world because of malaria alone. The plasmodium malarie is a tropic plant. It requires abundance of moisture, fertile soil and heat. Where the jungle is impenetrable, where dense forests struggle upward and shut out the light, where fierce storms and unbearable sunshine divide the equatorial day, the conditions of its existence are perfect. It is hard for us of the North, accustomed to the disease in its milder manifestations, to realize what a deadly scourge it becomes beneath a tropical sun. In the immense basin of the Congo and its tributaries, and in that of the Amazon in South America, the disease is seen at its worst. It has caused more human misery and suffering than any other one entity.

It is impossible to say at what period malarial fever was differentiated from other febrile disorders. Writers of antiquity have described the disease sufficiently well to show that they were perfectly acquainted with its clinical features. Certain it is that it prevailed very severely in ancient Rome, owing to the climate, the proximity of marshes and absence of sanitation. The fact that the Romans had a god "Febris," and a god "Mephitis," who presided over noxious exhalations, would seem to indicate a suspicion at least of cause and effect. It was late in the seventeenth century, however, before the true conditions were approximately understood. Even then, and for long afterward, exhalations, or impure air, or gas arising from marshland under a hot sun, constituted the supposed cause. Gradually the opinion obtained that the cause was a tangible one. Constant search was made for years by careful microscopists for the supposed bacillus. Announcements were made from time to time that the search had been successful, only to be controverted later on. Like an illusive "will o' the wisp" the little intruder had eluded their eager grasp.

It remained for Laveran, in 1880, to show the cause to be an actual organism—the plasmodium malarie. Subsequent observation has confirmed the accuracy of his claim. The matter may be considered as definitely settled. The life history of the plasmodium outside of the human body is still unknown. The universality of its distribution and rapidity of its development would indicate that it is easy of propagation. It is, however, a hot weather organism, and two weeks are required, other conditions being favorable, before the germs are produced in quantity sufficiently great to poison the air. It nearly always gains access to the human organism by inhalation. After having

effected a lodgment, it attacks the red blood cells. As it grows it causes a separation of the hemoglobin, and destroys the cell by segmentation. Spores are then liberated that in turn attack new cells, and thus the cycle goes on. From the time the cell is invaded by the plasmodium until its complete destruction, is but a few hours. It will thus be seen why profound anemia so soon ensues. The cells are destroyed much faster than they can be produced. The "chill" corresponds in time with the liberation of a new crop of spores, either by reason of the spores themselves, or of ptomains that are liberated at the same time. The liver and spleen, especially the latter, become enlarged sometimes enormously. The enlarged spleen may persist for years, or for life. The enlargement is caused by the deposit of separated hemoglobin, and the irritation incident thereto.

It does not effect man alone, animals also are attacked. Horses in India die of it. Stanley relates that the donkeys used to carry burdens in the Congo country were susceptible. It is of interest to note that Stanley's negro carriers were invariably attacked with malaria when taken into a strange locality, although that locality was not more unhealthy than the one from which they came. He also relates that getting wet, either by fording streams or by the rains that are so heavy in the African tropics was sure to cause an outbreak of fever. Among the farmers of our own country an attack is often precipitated by working in corn or other crops early in the morning while still wet with dew. The "old settler" in Indiana remains in bed until the sun is up.

Many conflicting traditions exist in regard to the discovery of the medicinal property of cinchona bark. It is named from the Countess of Chinchon, wife of a Spanish governor of Peru, who upon her return to Spain brought with her a quantity of the bark. It is maintained, erroneously I think, that the natives of Peru were cognizant of its febrifuge properties. After carefully investigating all the old stories connected with its early history, it seems reasonably certain that the discovery was made by the Jesuits. The Jesuits followed closely upon the footsteps of the armed men who over-ran this country shortly after its discovery; very often they were themselves the pioneers. They were men of considerable attainments in the natural sciences, and some were good botanists. While preaching the Cross, they made a study of the natural products of the new continent. The bark was brought by them to Rome in considerable quantities, about 1630, and introduced widely through members of the order. Hence the name "Jesuit's powder." The source and identity of the drug was maintained as a secret at first. Mystery adds to the zest with which the general public hails a new "cure" even now, but in the seventeenth century it was infinitely more true. The attitude of the medical profession to the new remedy is not a matter of which we may feel proud, although to our credit be it said, that among the physicians at that time whose achievements in other lines have brought their names down to us, the new remedy found support. Among them was Sydenham. The large quantity necessary to be taken as a dose was objectionable. In 1820 this objection was removed by the separation of the alkaloids by Pelletier and Caventou. The four alkaloids quinia, quinidia, cinchona and cinchonidia possess nearly equal antiperiodic powers. From force of habit probably, quinia is the one usually prescribed. Extensive and careful experiments made in India a

few years ago in the British army, with the view of determining the relative merit of the alkaloids showed very little or no difference.

It soon became evident that the trees in their native habitat were doomed to early destruction. The demand for bark was great; the trees were felled, stripped and destroyed. Much wastefulness prevailed.

The English anticipated this condition of affairs by putting out large plantations in India; choosing situations that in altitude, temperature and humidity closely simulate the conditions that prevail in its Peruvian home. The experiment has proved a successful one. It is a curious fact that the yield of alkaloids is increased 10 per cent. by wrapping the bodies of the trees with cotton or other loose substance for some time before they are "barked."

The treatment of malaria consists in giving one of the alkaloids of Peruvian bark. It is immaterial which one, provided it is given in doses sufficiently large, say 0.15 to 1.3 grams twice a day. Two large doses each day is better treatment than small doses given at shorter intervals. A full dose of opium should be added to each dose of the antiperiodic. Opium possesses decided antiperiodic properties. It also conduces to the patient's comfort. The bowels should be moved twice or thrice daily, that the debris of disintegrated blood cells and ptomains may be eliminated. A very useful agent in the treatment of malaria is Warburg's tincture. Two preparations are on the market, one with aloes and one without. The one with aloes is to be preferred. It is the best agent with which to keep the bowels open. It should supersede calomel. Especially is it useful if there is jaundice. It is an excellent prophylactic. Added to the headache and lassitude present when malaria is impending, there is often some jaundice observable about the conjunctiva, a peculiar "muddy" color of, and bad odor from the skin, and constipation. The alvine discharge is ash colored or white. The biliary secretion is decreased. It is in cases of this type especially that Warburg's tincture is useful. It should be given in doses sufficiently large to freely move the bowels, and continued in doses such as will keep them open. As the Warburg's tincture contains only 0.65 grams of quinin in 31 grams of the mixture, there should be given in addition two 0.32 gram doses of quinin daily. The disagreeable taste of quinin makes it objectionable to children. This difficulty can be obviated by administering quinia glycyrrhizin—a chemie union of quinin with glycyrrhizin. This salt is practically tasteless, and is soluble in water or syrup. The quinin combines with the glycyrrhizin in such proportion that four times as much should be given as of the sulphate.

In this latitude it is never necessary to give quinin hypodermically. In the South it is often demanded. If the case is very urgent, or a congestive chill is impending, it should be given hypodermically, notwithstanding the fact that this form of medication will in all likelihood be followed by abscess.

If the temperature is not very high the sponge bath, given frequently, will suffice as an antiphlogistic measure. Should it be necessary, acetanilid in 0.32 gram doses may be used as additional means for reducing temperature. Refrigerant drinks are also useful, as lemonade or "lime-juice and pepsin."

During convalescence the patient should have an abundance of food that is nourishing and easily assimilated. He should also have some ferruginous preparation, as the ferrous carbonate. After convalescence

is thoroughly established, quinin may be discontinued and tinctura cinchonæ compound given instead.

Continued fevers, that are not typhoid, are often encountered in malarial districts, over which quinin seems to exercise no influence. They can not be classified as "irregular" malarial fevers for this reason, and because an examination of the blood does reveal the plasmodium, either in its regular or irregular (æstivo-autumnal) form. They are probably caused by an organism different from but closely related to the plasmodium.

For the enlarged spleen but little can be done by medication. Time will help the matter somewhat.

For chronic malarial poisoning a change of residence, either temporary or permanent, to a colder climate is demanded.

INFLAMMATION OF THE UVEAL TRACT. CONSIDERED IN ITS ANATOMIC RELATIONS.

Read before the McLean County Medical Society, May 5, 1898.

BY J. WHITEFIELD SMITH, M.D.

Ex superintendent of the Illinois Asylum for Feeble-minded Children;
Member of the American Medical Association, Brainard District
Medical Society and McLean County Medical Society.
BLOOMINGTON, ILL.

The choroid, ciliary body and iris, taken together, form the middle tunic of the eye, and is called the uvea or uveal tract. This may be considered embryologically and histologically, as forming a continuous membrane. If we remove the conjunctiva, sclera and cornea from the globe of the eye, and evacuate its contents—the aqueous humor, lens, lens capsule, vitreous humor, and detach the retina from the choroid—we shall have left, depending upon the optic nerve, the uvea. It gets its name from its fancied resemblance to a grape hanging upon a vine (*uva*). The microscopic anatomy presents a striking similarity throughout its entire structure. There are, however, some variations, which may be noticed before considering the inflammation in its respective portions. Beginning with the choroid *in situ*, we find that it comprises the posterior section of the uvea, extending from the aperture of the optic nerve to the ora serrata. At the optic aperture its termination is marked by a delicate ring of cellular and elastic fibers surrounding the nerve and firmly adhering to the sclera. Also, a few fibers are sent to the neurilemma of the optic nerve and to the lamina cribrosa. At the ora serrata the choroid is continued into the ciliary body. The termination of the choroid proper at this point, is marked by the limiting denticulated border of the retina which underlies it.

The choroid is situated between the sclera and the retina, and is essentially a vascular body. It is composed of four layers: The suprachoroid or lamina suprachoroidea is the outer layer and forms the attachment to the sclera. It is a non-vascular membrane, containing pigment and lymphoid cells. The next layer is the layer of large vessels, consisting principally of veins which communicate freely with each other. The spaces between the veins contain pigment cells of a brown color. The arteries lie on the inner side of the veins. The layer of medium sized vessels forms the next layer and it is but slightly pigmented. The small blood vessels or the layer of capillaries (*tunica Ruyschiana*) constitutes the next vascular layer of the choroid. These are closely

packed together and contain no pigment. The lamina vitrea forms the inner coat of the choroid; it is also devoid of pigment cells. The framework uniting the vessels of the choroid is composed of delicate connective tissue.

The arterial vessels entering into the formation of the choroid are the short posterior ciliary arteries. These are about twenty in number and are derived from the ophthalmic artery. They pass through the sclera in a whorl or circle, close to the optic nerve, dividing into branches and passing forward for some little distance, where they change their course obliquely inward, terminating in the capillary layer. The venous system lies on the outside of the arteries and is arranged in curves (*vasa vorticosa*). They unite, forming four or five principal trunks, which pass through the sclera about half way between the corneo-scleral margin and the optic nerve.

The nerves of the choroid are branches of the ciliary, about fifteen in number. These are derived from the ciliary ganglion and the nasal branch of the ophthalmic division of the fifth nerve. They pass through the sclera near the optic nerve entrance, passing forward between the choroid and sclera, lying in immediate contact with the former, and partly imbedded in grooves, on the inner surface of the latter. They send branches into the choroid, in which they form a gangliated plexus.

The continuation of the uveal tract from the ora serrata to the peripheral or attached border of the iris is known as the ciliary body and consists of two portions, the ciliary muscle and the ciliary processes. The ciliary muscle is composed of two kinds of fibers, which accordingly divides it into two portions, the longitudinal or meridional fibers (*Brucke's portion*) and the circular fibers (*Muller's portion*). The ciliary processes consist of duplications or folds of the choroid. There are about seventy in number, arising near the ora serrata and extending forward to near the equator of the lens. They are arranged parallel with the meridians of the eye. The framework of the ciliary processes is of connective tissue. The ciliary processes are the most vascular part of the eye. They are covered on their inner surface by three layers—the hyaline lamella; a layer of pigmented cells, the pigmented epithelium; and a row of non-pigmented cylindrical cells. The last two rows of cells are a continuation from the retina and are called *pars ciliaris retinæ*. The blood vessels of the ciliary processes are derived principally from the anterior ciliary arteries, five or six in number. These arteries are supplied from the muscular and lachrymal branches of the ophthalmic artery. Perforating the sclera near the sclero-corneal margin, they divide into branches supplying the ciliary body, and assist in forming the *circulus arteriosus iridis major*.

The venous system is in connection with the *vasa vorticosa*. The nerves of the ciliary body are derived from the ciliary nerves, which form a dense plexus in the ciliary muscle; some fibers from the trigeminus also supply the ciliary body.

The portion of the uvea remaining to be considered is the iris. This springs from the anterior surface of the ciliary body. The stroma composing the iris consists of a connective tissue or cellular mesh work, containing numerous vessels and some pigment cells. Near the pupillary border of the iris on its posterior surface is a narrow circular band of muscular tissue

(sphinter pupillæ) whose function is to close the pupil. Also close to the posterior surface, beginning at the ciliary margin, the dilator fibers are found (dilator papillæ). The anterior surface of the iris is lined with an endothelium. This is a continuation of the endothelium of Descemet's membrane. The posterior surface of the iris is lined with a layer of pigment epithelium (pars iridica retinæ) and is continuous with the retinal pigmentary layer. The blood supply of the iris is derived mainly from the long posterior ciliary arteries, two in number. These arteries enter the eye near the optic nerve entrance, passing forward between the sclera and choroid. Each artery divides into an upper and lower branch just behind the peripheral border of the iris. The branches run concentrically with the margin of the cornea, uniting with the branches on the opposite side, forming the large arterial circle (circulus arteriosus iridis major). Near the pupillary margin they form by anastomosis the small circle (circulus arteriosus iridis minor). The long posterior ciliary arteries are branches from the ophthalmic. The venous system of the iris has a corresponding arrangement with the arteries. There is a communication between the canal of Schlemm and the veins of the iris. The nerves of the iris are the ciliary. They follow the course of the blood vessels and send off numerous anastomosing branches. Their termination is probably in the muscular tissue of the iris.

I have reviewed the anatomy of the three portions of which the uvea is composed in order that we may more fully appreciate the likeness and the differences of its structure throughout. It may be summarized thus:

UVEAL TRACT.

Choroid.	Ciliary body.	Iris.
Framework consists of a delicate connective tissue.	Same.	Same.
Consists largely of blood vessels.	Same.	Same.
Contains numerous pigment cells, brown.	Same, black pigment.	Same, light or dark pigment.
Nutrient function; furnishes nourishment for the retina, vitreous and lens.	Same, ciliary processes; furnish nourishment for vitreous and lens.	Same; assist in nourishment of lens.
Nerve supply; the ciliary nerves.	Same.	Same.
Muscular elements, absent.	Ciliary muscle.	Sphincter pupillæ and dilator pupillæ.
Blood supply; short posterior ciliary arteries, mainly.	Short anterior ciliary arteries, mainly.	Long posterior ciliary arteries, mainly.

Aside from the muscular elements which enter into the structure of the uvea, the chief differences are in the blood supply to the different parts. In the study of the inflammations affecting the uveal tract, we may understand from this the reason for the characteristic differences in the clinical phenomenon presented.

An inflammation originating in the choroid, chroiditis, is usually limited to the posterior portion of the uvea—the choroid proper. It is not apt to pass over to the ciliary body and the iris. This is especially true of the exudative or non-suppurative form. The question may be asked, why this is the case, since the uveal tract is essentially a continuous membrane and so similar in structure throughout? I think the difference in the blood supply to this portion furnishes the answer. We might reasonably expect, but for this reason, that the inflammation would be continued forward by continuity of tissue. In the suppurative forms of chroiditis, the ciliary body and the iris become involved (irido-choroiditis), but the extension seems to be due to the violence of the inflammation, and probably to pyogenic infection, producing,

in many cases, panophthalmitis with subsequent shrinking of the globe (phthisis bulbi). Again, an inflammation originating in the anterior portion of the uvea—the iris (iritis), is not so likely to be transmitted to the choroid, for the same reason. The blood supply to the iris is almost independent of that of the choroid.

An inflammation of the iris may be confined entirely to the structures of which the iris is composed. It is, however, very frequently accompanied by an inflammation of the ciliary body (irido-cyclitis). This may be accounted for by the fact that the blood supply of the two portions of the uvea, is in part, from a common source. The blood passing through the two long posterior ciliary arteries is distributed almost entirely to the iris. It is true that the circulus arteriosus iridis major is in connection with the anastomosing branches of the anterior ciliary arteries, and that the major circle sends some branches to the ciliary muscle, and in this way there is a connection between the iris and ciliary body in their blood supply, as well as in their anatomic elements. An inflammation beginning in the iris is less liable to be extended to the ciliary body than one originating in the ciliary body, is to be transmitted to the iris. This is probably due to the complexity existing in the blood supply to the respective parts. As we have already seen, the five or six anterior ciliary arteries enter the globe about two millimeters behind the sclero-corneal margin, where they divide into branches, and supply the ciliary processes, and join the major circle. Hence, the iris is somewhat freely supplied by the branches of the anterior ciliary arteries, more so, perhaps, that the ciliary body is supplied by the two long posterior ciliary arteries. Also, numerous small vessels extend from the ciliary processes to the iris, supplying the latter. In the consideration of inflammation affecting the middle portion of the uvea—the ciliary body—it is authoritatively stated that "simple cyclitis, without iritis, occurs but seldom and that only in the chronic form." I think the blood supply to these parts accounts for this. There seems to be a more intimate and intricate connection in the blood supply from the ciliary body forward to iris than exists between the iris and the ciliary body in a posterior direction. It may be further noted that an inflammation arising in the ciliary body is not so liable to be extended to the choroid as it is to the iris, and for the reason already given.

There are other factors that chiefly determine the tissue alterations in an inflammation of the uveal tract. Among them may be mentioned the distribution of the lymph channels and lymph spaces. Lymphatic vessels do not exist within the globe of the eye. Lymphoid cells are found in the lamina suprachoroidica, and a lymph space is located between the sclera and the choroid. This lymph space is in connection with Tenon's space. The distribution of the lymph in the region of the choroid is through the posterior lymph passages, in the direction of the optic nerve. The lymph collected in the anterior part of the eye, in the region of the ciliary processes and the iris, passes through ligamentum pectinatum, through Schlemm's canal, and finally is distributed to the anterior ciliary veins. Thus the lymphatic arrangement and circulation becomes an important element in considering inflammations in the different portions of the uvea. The chief thought which I wish to emphasize is that the blood supply to the

various portions of the uvea is a predominating and determining factor in the limitations and complications of an inflammation affecting the uveal tract. The complexity of the blood supply to the choroid, ciliary body and iris makes it all the more difficult to apply general statements to this etiologic factor in inflammatory processes. However, regarding the blood current as a conveying medium in inflammation of the uvea, I think that the course and the clinical phenomena are all the more easily interpreted by directing our attention to the blood supply of the respective parts.

An area of inflammation may be limited or confined to the part in which it originates. This is rendered more probable in proportion as the blood supply is less complicated with other portions. It may also be extended to all portions of the uvea, in which case the inflammatory process will be largely influenced in the directions, relations and in conformity with its vascular connections.

A very close sympathy must always exist among the component parts of the uvea in pathologic changes of any portion of its anatomy.

A CASE OF ANEURYSM OF THE LEFT VENTRICLE.

BY ERNEST B. SANGREE, A.M., M.D.

Professor of Pathology and Bacteriology in the Medical Department
of the Vanderbilt University,
NASHVILLE, TENN.

Recently Dr. W. H. Witt, Demonstrator of Anatomy, found in the body of a colored woman of about 25 years, the cardiac aneurysm shown in Fig. 1. The surface of the heart was covered with shaggy fibrin

of a recent pericarditis, but whether or not this was the cause of death we have been unable to learn, as the body was of the "resurrected" variety and we have not succeeded in tracing it so as to get a clinical history. The aneurysmal pouch when opened contained soft black clots, showing no attempt on the part of nature to fill it up with laminated clot. The pouch communicated with the cavity of the left ventricle by a large opening just below the attachment of the anterior segment of the mitral valve. This opening is two and three-fourths centimeters long by one and one-fourth broad (see Fig. 2). The opening easily

admits the tips of the thumb and two fingers. The edges of the orifice are markedly hard, smooth, rounded and in places fibroid, the appearance being that of a lesion of long standing. The dimensions of the pouch are: length twelve centimeters, width eight and height seven centimeters. The left ventricle is both hypertrophied and dilated, its wall being one and one-fourth centimeters thick and its cavity notably large, the interventricular septum giving the appearance of having been pushed toward the right in such a way as to lessen the cavity of the right ventricle. On account of the marked postmortem change, nothing

definite could be ascertained in regard to the heart muscle microscopically, but so far as I could see it was normal. There was no evidence of atheroma in the aorta, and the other organs gave no signs of syphilis. The walls of the pouch consisted only of thickened epicardium, the muscular tissue having evidently been broken through. As for the cause, it was probably an embolus or thrombus in a radical of the coronary artery, which by its occlusion gave rise to a myomalacia, and the disintegrated heart muscle disappeared, allowing the blood to push against and gradually dilate the visceral pericardium.

CREMATION.

BY GILBERT I. CULLEN, M.D.

CINCINNATI, OHIO.

Cremation, or the burning of the bodies of the dead, may be said to be an ancient custom with all countries excepting Egypt, where they were embalmed, Judea, where they were buried in sepulchres, and China, where they were buried in earth. In Greece only suicides, unteethed children and persons struck by lightning were denied the right of burial. At Rome one of the Twelve Tables said *hominem mortuum in urbe ne sepelito neve urito*, and in fact from the close of the republic until the end of the fourth century burning was the rule, although Macrobius says it was disused in the reign of Theodosius.

The Chinese were influenced by the doctrines of Feng-Shui, which taught that they must be buried in a grave on their own land, hence, the Chinese who die

in California are sometimes sent to their homes for burial. Even the Jews used cremation in the Vale of Tophet when a plague came, while those at Berlin and the Spanish and Portugese Jews at Mile End Cemetery have been among the first to welcome the revived process. Probably some nations had religious objections to pollutions of the sacred principle of fire and therefore practiced exposure, suspension, throwing into the sea, cave burial, desiccation or envelopment. The Colchians, says Sir Thomas Browne, made their graves in the air, *i. e.* the trees. Cremation, while practiced over a great portion of both Asia and America, is not always uniform in procedure. Thus with some the ashes are stowed away in urns or buried in the earth, or strewn upon the ground, while with others curious customs are followed, as with the Digger Indians, who smear the ashes, mixed with gum, on the heads of the mourners. The Siamese have a rule by which the body, being embalmed, lies in a temple for a period which is determined by the rank of the dead person, the king for six months. In the event of the relatives not being able to have the body cremated, it can be buried and exhumed when the opportunity affords.

There can be no doubt that the practice of cremation has been prevented in a great measure by the Christian doctrine of the resurrection of the dead. Science has, however, shown that burning merely produces in a short time what putrefaction takes a much longer time to accomplish, but the feeling of opposition still lingers among many of the clergy. Some writers have been prominent in this reform movement, as for instance Mr. Hawers, who has expressed some very decided views in his work entitled "Ashes to Ashes."

The very general practice of burying the dead in the immediate neighborhood of a church, in order that they might have benefit from the prayers of persons attending, and the ceremony which precedes both the Asiatic and American form of cremation, have given the question a decided religious aspect in the minds of many. Cremation is really a much more sanitary procedure. The disgusting results of pit burial made cemeteries an absolute necessity, but cemeteries are equally liable to overcrowding, and are frequently nearer to inhabited houses or settlements than the older churchyards. It is possible to make a cemetery approximately safe by selecting a soil which is dry, close and porous, by careful drainage and by a rigid enforcement of the rules requiring a certain depth, eight or ten feet, and a certain surface space. But one has only to read Baker's laws relative to burial, to realize how many dangers burial legislation has to contend with. A certain amount of irrespirable gas will escape into the air or into the sewage drains, and thus reach houses, or will percolate through the soil to the extent of contaminating the water used for drinking purposes. An investigation has revealed that the residents in the immediate vicinity of the large Paris cemeteries are peculiarly prone to headache, diarrhea and ulcerative sore throat.

A dense clay soil is best for preventing levitation of the gases, but the worst for the process of decomposition. It must also be remembered that the cemetery system can only be temporary, the soil is gradually filled with bones and the encroachment on the cemetery property by newly erected houses, progresses day by day. The law itself permits the reopening of a grave after having been closed for fourteen years.

From the standpoint of sentiment it must be admitted that cremation would effectively prevent any interruption to "that sweet sleep and calm rest" which the old prayer "that the earth might lie lightly" has associated with the grave, while in addition we would escape the horror of putrefaction and of the "small cold worm that fretteth the unshrouded form."

For the past ten years many distinguished physicians and chemists have warmly advocated the adoption of cremation in Italy. In 1874 a congress was called at Milan to consider the matter, and a resolution was adopted petitioning the Chamber of Deputies to permit cremation to be practiced under the direction of the chief official having charge of that department.

In Switzerland, Dr. Vegman Ercolani is the champion of the cause, and there are two associations organized for its support. In 1797 this matter was extensively discussed by the French Assembly, while in Vienna the strong opposition has been overcome and cremation is now permitted, and in Berlin, Dresden and Leipsic there is a strong movement in favor of it, which is emphatically endorsed by Professor Reclam's last work upon the subject. In Great Britain the matter has slumbered for two centuries, since 1658, when Sir Thomas Browne published his book on "Hydriothopia or Urn-burial." In 1817, Dr. J. Jamieson gave a sketch of the origin of cremation, and for many years prior to 1874 Dr. Lord, medical officer for the health department, seems to have had the adoption of it. It was Sir Henry Thompson who first brought the subject prominently before the public, by organizing the Cremation Society of London. He also pointed out the danger of infection of air and water around cemeteries. The British authorities in India have already had much experience with cremation in that country, and Sir Cecil Beadon, together with the sanitary commission at Madras, have found it necessary, in the public interest, to erect cinerators, which might be used on the payment of a fee. At Poonah, in 1864, Colonel Martin constructed a pentagonal cinerator to obviate the excessively high cost of burial, which is generally above twelve rupees.

The Egyptians used a shroud of amianth, while the Greeks encased the bodies to be burned in asbestos.

The discussion which has recently been going on in Europe relative to the propagation of disease germs through the medium of the earth worms, will no doubt tend to greatly stimulate the interest in and support of cremation.

SOCIETY PROCEEDINGS.

Maryland Public Health Association.

Meeting held at Baltimore, May 11 and 12, 1898.

Dr. WILLIAM H. WELCH, president, in the chair and Dr. JOHN S. FULTON, secretary.

Dr. WELCH spoke of the age of the Association, started last year, and thought the only thing needed now is a large and influential membership to render this organization a power to demand and obtain anything that is for sanitary good of the State. We have already accomplished some practical results; we made some demands at our last meeting and the legislature has given us a vital statistics law, better than no law at all; and now we have a law which enables the State Board of Health to start a bacteriologic laboratory; this will enable us to investigate outbreaks of disease throughout the State. The diagnosis of tuberculosis, typhoid fever, etc., will be made for physicians throughout the State. This great work will stand in relation to public education and preventive medicine and it will stand on a sound scientific basis, with good laws and well

trained and good officers to administer these laws. Public opinion and effective legislation are necessary to secure the benefits of these laws, and we need in addition, the training of experts in public health as they exist in England. Training medical men does not necessarily carry with it the knowledge of sanitary science. This subject is being agitated and steps are being made to take those who would be trained in this department. The University of Pennsylvania has started a department looking to a degree for those who are expert in sanitary science. Organizations will accomplish these results and a National organization is important. We lack this; we have none here. We should have a department of public health, but there are reasons, partly political, why physicians have not been able to accomplish this. It is interesting to note how sanitation is effective, not only in solving many of our important medical problems, but in bringing about better health and greater contentment also. He spoke of the organization of a village inspection society, which was started by Mr. Northrop in New England, and said that such a thing might be done in this part of the country. In all this work, however, women are and must be a very important factor; they can be the important instrument in securing these results.

Dr. JOSEPH E. GICHNER and Dr. MELVIN S. ROSENTHAL of Baltimore then read papers entitled

THE SWEAT SHOP IN ITS RELATION TO PUBLIC HEALTH.

Dr. GICHNER said that we should look at the matter from all sides. The definition of sweat-shop varies; some so-called sweat-shops are really not sweat-shops, and *vice versa*. Charles Kingsley, in "Alton Locke," has given us a very clear picture of sweat-shops in those days. A sweat-shop is a place where a number of persons work under pressure and for a minimum wage, while comforts are not considered; it is generally contract work and it is usually in shops at home, and the dangers are from working at home. The condition of affairs in New York is very bad, but in Baltimore it is not so bad, on account of the small houses and the cheap rents. The Baroness Hirsch gave \$1,000,000 to build cheap homes outside of New York, rent them at moderate prices and attract factories. In the city some of the worst sweat shop houses bring better rents than many larger houses, on account of the enormous number of persons which may be crowded into a small space. He then gave the limits of the sweat-shop system in Baltimore. This is the congested district, but strange to say there is not much diphtheria and scarlet fever, while the child mortality is not very high; there is very little insanity and the general moral tone is not so low as one would expect; consumption, however, is on the increase in these sweat-shops, but the disease is not carried away by the clothes, on account of the pressure during ironing with a hot heavy iron in a hot room. The iron prevents, in part, the spread of the disease to these people; he spoke also of Russian Jews having a great love for their children. The charities providing free milk and ice have had good effects in decreasing the amount of tuberculosis. Many cases occur after the people come to this country. Unaccustomed to working in a small room, on a sewing machine, and the hard work, stooping position and dust inhalation, all tend to cause the disease. While they are a menace to the community in a certain way, still the bad effects react principally on themselves. It is extremely hard to do anything for these people through the health department, because they are dependent on their work and resist every attempt at inspection.

Dr. ROSENTHAL said that those who work in factories were usually fairly well provided for, while those who work in their own shops, and for wages, were usually the worst off. They usually work from twelve to fifteen hours a day, and in winter the rooms are almost air tight, with men smoking cigarettes and probably spitting all over the floor. We ought to enforce the law and report the cases of tuberculosis, but this is almost impossible. In some places placards are posted outside of the door that contagious diseases are there. The public should be protected from the dangers of these diseases.

The next subject taken up was

THE NEED OF A HOSPITAL FOR INFECTIOUS DISEASES.

This was presented by the Health Protective Branch of the United Women of Maryland. A letter was first read from Dr. HENRY M. HURD of the Johns Hopkins Hospital, speaking of the urgent necessity of such a hospital.

Dr. JOHN S. FULTON, secretary of the State Board of Health, said that public feeling and private interest alike demanded defenses against whatever threatened the welfare of society. We provide against fire, crime, want and ordinary sickness, and yet we leave the hospital for such diseases as diphtheria, scarlet fever, etc., unbuilt. The health commissioner has some difficulty in knowing what to do with cases of this kind. Cases are usually reported by physicians, but any attempt to

quarantine the family is fruitless and the disease may be, or is, actually carried in numberless ways, for if the city quarantines any family it must necessarily pay this family for any pecuniary loss. The trouble is we are too familiar with these diseases to be frightened by them. The cost of an infectious disease hospital would be necessarily great at first, but not as much as now dealing with individual cases. Such a hospital must be accessible, but almost every one objects to a hospital near them. Everything in this hospital should be free, and the city should bear all cost. Persons who would wish special accommodations and private rooms would necessarily have to pay for them.

Dr. WILLIAM ROYAL STOKES, city bacteriologist, spoke of an ideal infectious hospital. He said in such a hospital cases are brought into an observation ward and kept there until it is seen which disease will develop. The case is then sent to the proper hospital, after the diagnosis is made; the observation room is then disinfected and cleaned before any other patient is admitted. Each department for such diseases as measles, scarlet fever, etc., is kept entirely separate, the nurses being separate and every department being cut off from the others; after the patient is convalescing he is taken to another room with cases of the same kind, and is kept there until the period of infectiousness is over, that is, until the germ has disappeared. Smallpox is not treated at such hospital, but in a separate institution entirely.

Dr. C. HAMPSON JONES, health commissioner, then related some of the difficulties in carrying out his work.

Dr. WILLIAM J. TODD, health officer of Mt. Washington, said that infection was often carried by innocent persons and to innocent persons, and spoke of a very clear case by which some papers had been the means of carrying scarlet fever to a family.

Dr. WILLIAM H. WELCH, the president, said that the absence of an alarming tone in the papers of Drs. Gichner and Rosenthal were very gratifying; the fact that the clothing is sterilized before distribution, by the hot iron and the hot room is exceedingly interesting and had never occurred to him before. Nevertheless, danger from tuberculosis to those working in sweat shops is a real one and it is an important matter. It is gratifying to notice that there is a diminution in the death rates from tuberculosis; the death rate among the Hebrews is smaller than among others, and the contagion in the rooms might be accounted for by a theory of Flügge of Breslau. He says that the dangers from the dried sputum in spreading tuberculosis are not so great as the dangers from coughing; in the action of coughing, sneezing and hawking one sprays from the throat a fine moisture, which emitted from the mouth floats in the atmosphere for many hours. This Flügge thinks is more dangerous than dried sputum. Probably this may explain the great danger of contagion in small rooms like the sweat-shops. In New York the board of health has power to close a room where a case of tuberculosis has died, that is to say, in tenement houses or small lodging houses, and these premises are disinfected, cleaned and kept vacant for a time at the expense of the owner. The need of a hospital for infectious diseases in Baltimore does not call for much discussion. He had brought this up in an address two years ago and it had passed the city council and become a law, and \$30,000 had been appropriated, but no suitable location in the city could be found, as every one objected to the proximity of such a building. It must be accessible to be of use. He thought it was a bad plan to call it an infectious hospital or pest house, or such names, but municipal hospital would be a good name. There is no danger from contagion in such a hospital except perhaps from smallpox to the unvaccinated, and smallpox should never be treated in these hospitals. He thought that we should consider these subjects from a sanitary point of view only and not from an economic or business point.

Dr. WILLIAM B. CANFIELD thought the subject of sweat-shops should be considered from all sides to be practical. He had not noticed that in any papers read any reference had been made to the origin of the sweat-shop; there must have been some reason for calling it into being, and he thought it was partly because of late there had been a greater demand for cheaper clothing both for men and women, but especially for men, and this demand could only be satisfied by working the poor people in the shops. He thought that every man or woman who bought cheap clothing helped the sweat-shops.

Dr. SAVAGE, who is the physician to the Hebrew Benevolent Society of Baltimore, said that the sweat shop is an American institution and of recent origin; he had seen a large number of cases of tuberculosis resulting from sweat shop infection.

Dr. BROWN of New York, said that he thought many of these children of the sweat-shop workers escaped disease by prophylaxis; they are predisposed to the disease and contract it from

a general lowered vitality and a tuberculosis infection. But the fresh air societies in the city, and the free milk and ice, have all contributed to keep these children alive beyond the danger point. In New York the case is either removed from the house or else the house is placarded.

Dr. EDWARD M. SCHAEFFER said that all of these questions came back to the point of public enlightenment. Massachusetts says she has no sweat-shops, which is probably true.

Mrs. FENDLER said that such a model hospital as Dr. Stokes described existed in New York, the Willard Parker Hospital on Sixteenth Street; this is used as a reception hospital, only the cases which develop being taken to North Brother's Island. She said that the anti-expectoration law which had been passed in New York and Baltimore and other places had been very effective in Baltimore so far, but the street railways had prepared and were about to post cards calling attention to this law and forbidding spitting on the floor under penalty; and the United Women of Maryland were about to send out a number of watchers of detectives to have persons breaking this law punished.

Dr. HOWARD BRATTON, health officer of Elkton, related a case of infection the cause of which had been very difficult to trace.

Dr. GICHNER read several of the laws of Maryland in regard to sweat-shops, which showed that the laws were excellent if they were only enforced.

Dr. AUGUSTUS STABLER, health officer of Brighton, said that there must be concerted action to obtain any results; if the laws were good they ought to be enforced.

Dr. FLORA POLLOCK spoke of a case of scarlet fever in which the inspector called and it was a farce.

Dr. WILLIAM J. TODD of Mt. Washington, read a paper entitled "Vaccination and Revaccination," in which he said that vaccination and revaccination were not sufficiently regarded at the present time; too often certificates were given when there had been no proper vaccination. He thought that revaccination should be done at least once every twelve years, and oftener in many cases. This paper was discussed by Dr. Welch and Mr. Hartshorne.

Mr. CHARLES R. HARTSHORNE, school commissioner of Montgomery County, read a paper on

SCHOOL INSPECTION.

In his district, none of the buildings have a cubic air-space commensurate with the seating capacity; the room that was supposed to be best ventilated was found to be very close and uncomfortable. In only one school were the children required to use individual drinking cups, but since that investigation other schools have adopted the plan. There has also been a greatly improved way of reporting the infectious diseases and the prevention of children from returning to school before a safe time after illness. In nearly every school the desks are antiquated and improperly arranged, in many cases the children being obliged to bend forward at a considerable angle in order to see the book.

Dr. AUGUSTUS STABLER, health officer of Brighton, said that in private houses heating is not so difficult, but in public buildings occupied for only a part of the day, especially in country districts, the floor is usually cold except in proximity to the red hot stove. Air soon becomes impure, windows are open, cold draughts come in and often cause illness. Nothing but ignorance can cause such conditions as these. In ventilating small school houses two things should be utilized: 1. Fresh air must be furnished through a flue placed under the stove, and this inlet should have a valve to regulate the influx of air, but should never be shut tight. 2. A ventilating chimney should be put on one side of the room, and if the stovepipe is inserted near this aperture the waste heat escaping will create a draught. If the building is already erected and the funds are limited, then the placing of a simple chimney made of plain boards, on the corner of the room and carried several feet above the roof and surmounted with a suction cap, answers the purpose. These have been found to work in rooms for thirty or more people. The opening near the floor should be the full size of the chimney, and the size of the chimney should be governed by the number of people who are to occupy the room. If there is not sufficient current, then a small lamp should be put inside of this chimney. Our children need not only free schools and free books but free ventilation.

Miss McILVAIN read a paper for Miss RIDGELY, representing the Health Protective Branch of United Women of Maryland, describing the system of medical inspection which had been employed in Boston and other cities, which had caused diminution in the number of contagious diseases in the schools.

Dr. JOHN S. FULTON showed a device which he had for the ventilation of small rooms. It was a tin pipe within another pipe to be attached to the stove.

Mr. WORTHINGTON, school commissioner of Anne Arundel County, asked when the child was vaccinated if a certificate was given at that time?

Dr. FULTON said that a certificate only showed that the arm has been scarified and something rubbed on it.

Mr. WORTHINGTON said that if the child is not vaccinated it is the physician's fault.

Dr. TANEYHILL asked what reform would be suggested in this case?

Dr. WELCH asked if the certificate was given at the time of vaccination or when the arm was looked at?

Mr. WORTHINGTON said that it is usually not given until he is satisfied that vaccination has taken place.

Mrs. FENDLER said that in New York physicians go to every school and examine every arm, and send those who need it to be vaccinated. They visit the school again in a few days and see what the results are.

Mr. HARTSHORNE said that revaccination was very important and of use, but there should be some modification of the law. Some physicians give a certificate as soon as vaccination is done without seeing whether it takes; physicians should revaccinate every case that does not take. We must understand what "duly vaccinated" means. There ought to be a provision for revaccinating once in four to five to ten years. This carrying out of the law is placed on the shoulders of the teachers; this is a mistake, many of them being young women not paid much, and they have enough to do without this, and one would not think of fining one of these teachers unless in exceptional instances.

Dr. STABLER asked who should pay for the virus and the physician's work? He knew of no means provided in State or county for vaccinating children, and parents were not able to pay for it themselves; most of them do not want to do it if they can get out of it. It is too often a charity on the part of the physician; it is troublesome to do it properly; you first have to get your lymph and then catch your child. As it is done to prevent disease, the community should bear the expense, and there should be some stipulation in the law as to the kind of vesicle which is produced. As for Dr. Fulton's device, he does not like it, for if it is used, someone will think the building is ventilated and, though it may do the work, it is on a wrong principle.

Mr. HARTSHORNE said that an architect had just told him that Dr. Stabler was on the right track.

Dr. CHARLES W. MITCHELL of Baltimore, made some remarks on

PERIODS OF INCUBATION AND INFECTIOUSNESS.

He referred to the large number of cases attending the schools in the various cities, said inspection is possible with us in the large cities and towns, and gave definitions of the period of incubation, *e. g.*, the time between the entrance of the poison into the body and the appearance of the disease; this varies in different diseases and in the same diseases under different circumstances. The period of infectiousness is when the patient, by some of the discharges, retain the power of conveying the disease. He referred to the after effects and some of the discharges which may contain the disease, which may spread long after persons think it is passed. The infectiousness is just as dangerous in mild cases as in severe ones, and mild cases are the most dangerous kind because people do not recognize them. He protested against the idea which is prevalent of exposing children to the contagious diseases in order to let them get over it. In the outbreak of a disease mothers will bring other children in the same room and into the same bed so that they can have all the trouble of nursing them at once. This has too often caused the death of one or more of the children. He then went over systematically such diseases as measles, scarlet fever, diphtheria, whooping cough, chickenpox and mumps and showed the periods of incubation, the period of infectiousness and the general reaction of all these diseases.

Col. GEORGE E. WARING, at the evening session, delivered an address on

THE SANITARY TREATMENT OF WATER-BORNE WASTES IN TOWN AND COUNTRY.

He said that while we often pay attention to sanitary matters in the house, we neglect them outside. Sewage is unpleasant to the sight and to the smell, and still further it furnishes a growth of bacteria harmful to man. When foul liquid is thrown upon the ground it gradually loses its power of harm, but when discharge takes place in a cesspool dangerous putrefaction soon sets in. The cesspool is a source of danger in every place. The only proper disposal of sewage is to bring all of its organic contents into close contact with atmospheric air under conditions suitable for bacterial oxidation. There

can be no proper disposal that does not secure rapid resolution into elements. All decaying matter should be put in the way of being destroyed most quickly. If sewage be allowed to trickle over crushed stone, so arranged that air will penetrate all crevices, it will soon pass away as pure as water, leaving deposited a layer of sludge which is soon oxidized. Col. Waring then described a system of his own for disposing of sewage in country houses, which could be put up at small cost.

SECOND DAY.

Dr. EDWARD M. SCHAEFFER, representing the Physical Education Society of Baltimore, read a paper entitled "Wanted, a Man," a report of the physical training and hygiene in the schools. He referred to the necessity of physical training in schools as a means of making better students, and then he gave a detailed report of the different schools throughout Baltimore and Maryland.

Miss REBECCA STONEROAD, physical director of the public schools of Washington, D. C., read a paper on "Public Schools, Conditions, Problems and Methods." This paper was discussed by a number of the members.

After this the addresses of the morning were illustrated by exercises in physical culture at the schools. Several classes from the children's department, and also from the high school, went through various figures of the Swedish system illustrating the addresses.

Rev. T. M. BEADENKOPF read a paper entitled

PUBLIC BATHS IN EUROPEAN AND AMERICAN CITIES.

He spoke of the difficulty that boys had in Baltimore in going swimming, as they are always driven away by the police. By the aid of several gentlemen he had erected several bath-houses, the beginning of a system of public baths in this city. Europe is far ahead of us in the system of public baths. London is said to have expended two and a half million dollars in this deserving charity. They also have wash houses where soiled linen is laundered by the poor people, who pay a small sum for the privilege. This yields a large revenue to the city. He thought that the shower-bath was especially successful when introduced into the schools and he thought that the children who did not have baths at home would be very glad to use those at the schools. He hoped that the School Board of Baltimore would endeavor to establish free baths for the pupils. In New York there are a few floating baths on East River, which provide for bathing but not cleanliness. The taste for bathing is acquired, not natural. In the slum districts of Baltimore there is provision for about 9 out of every 100 persons for bathing in bath-tubs; in Philadelphia, 17 out of 100; in New York, 21, out of 100, and Chicago 4.

W. H. MORRIS, secretary of the Y. M. C. A., who is also a member of the City Free Bathing Commission, said that this work had begun about five years ago and even with limited facilities much had been accomplished: 30,000 men and boys used these baths last summer.

These two addresses were discussed by a number of members and several resolutions offered.

The following officers were elected for the ensuing year: President, George H. Rohé; vice presidents, Edward M. Schaeffer, Mrs. Daniel Miller, Miss Eliza Ridgely, Charles R. Harts-horne, Augustus Stabler, Howard Bratton; secretary, John S. Fulton; treasurer, L. Gibbons Smart.

Medical Society of the State of Pennsylvania.

The Fiftieth Anniversary, held in Lancaster, Pa., May 17, 18 and 19, 1898.

The President, Dr. W. MURRAY WEIDMAN of Reading, called the session to order at 9:30 A.M., and Dr. E. V. GERHART, President of the Reformed Theological Seminary, invoked the Divine blessing upon the members and their doings.

Mr. C. A. HEINTSH of Lancaster, extended the congratulations of the State Pharmaceutical Society, and referred to the fact that the first president of this body was Dr. Samuel Humes of Lancaster. He congratulated the Society upon the completion of its half century, and alluded to the fact that the meeting at which the Society had been organized was held in the city of Lancaster.

The address of welcome in behalf of the Lancaster City and County Medical Society was delivered by Dr. GEO. W. BERN-THIESEL of Columbia. He said it was eminently appropriate that this the semicentennial meeting should be held in the place of the Society's birth. He mentioned that the County Society of Lancaster ante-dated this Society, having been founded in 1844, and heartily welcomed the delegates and all to the hospitalities of the city. The other officers are: First vice-president, Wm. B. Atkinson, Philadelphia; second vice-

president, Wray Grayson, Washington; third vice-president, B. H. Detwiler, Williamsport; fourth vice-president, J. H. Bittinger, Hanover; secretary, C. L. Stevens, Athens; assistant secretary T. B. Appel, Lancaster; treasurer, G. B. Dunmire, Philadelphia.

Dr. A. R. CRAIG of Columbia, presented the program and other arrangements for the meeting. At this point a handsome gavel was presented to the presiding officer on behalf of the Committee on Legislation.

Dr. J. AUGUSTUS EHLE of Lancaster, one of the founders of the Society, was invited to a seat upon the platform. Dr. S. S. Towler, Chairman of the Committee on Scientific Business, reported the work of that committee to make this session a complete one in point of papers and attendance of members.

Dr. C. L. STEVENS, secretary, reported that there were fifty-seven county societies in affiliation with the State society, having a total membership of 3194; permanent members 1317.

The treasurer, Dr. DUNMIRE, read his report: Receipts \$3,717, expenses \$3,699, in treasury \$2,720. The Board of Trustees and the Committee on Publication reported requesting that all papers read before the Society first be printed in the official Journal, the *Pennsylvania Medical Journal*. This was agreed to.

The report of the Committee on Pharmacy commended the activity of pharmacists in improving their profession, and aiding so materially in assisting the medical profession. Regret was expressed that in a few instances druggists from mercenary motives have striven to lower the tone and the high standard established by their more conscientious and painstaking brethren.

An amendment was offered to the Constitution to change the time of the annual meeting from May to September. This was laid over until next year.

At the afternoon session Dr. H. S. McCONNELL of Brighton, read the "Address in Medicine." He treated it under two heads, therapeutics and dietetics, alluded to the progress in recent years of medical instruction and text books, and suggested to the younger members of the profession not to overdose their patients, as small and frequent doses have been found of greater value than large doses at long intervals. He believed in therapeutic fasting, and opposed therapeutic stuffing. Keep alimentary canal in an antiseptic condition.

Dr. J. M. BATTEN of Pittsburg read a paper on "Alcohol." He said this had been used from time immemorial, and that there is no nation but what uses some form of stimulant or narcotic, and alcohol in some form or other is a universal favorite. He gave a very entertaining account of the origin of alcohol, its use in ancient times and the different drinks to which nations are addicted. In view of the fact that alcohol has been much abused, he said that for hundreds of years after its discovery chemists considered it an invaluable adjunct to their laboratories.

Dr. T. J. MAYS of Philadelphia, followed with a paper on "The Ice Treatment in Pneumonia." He applies the ice to the chest in wide mouthed rubber bags, or wanting these, it may be wrapped in towels either with or without a mixture of snow and sawdust. One application usually lasts two hours. Ice to the head is also valuable. Internally, strychnia, morphia and quinia are to be administered in appropriate doses. The paper was fully discussed, some being decidedly opposed to this treatment, fearing a heart complication or the extension of the inflammation. Dr. Mays closed by citing many authorities and cases where the treatment had been successfully employed. His own cases had been markedly successful. Cold reduces the frequency of the pulse, tones up the heart: 85 per cent. are cured without other treatment, in fact a large percentage recover with very little medical treatment.

Dr. J. J. JOHNSTON of Pittsburg, read the particulars of a case of "Tuberculous Cirrhosis of the Liver," giving the diagnosis of a case which had occurred in his practice and the autopsy.

Dr. H. BEATES, JR., of Philadelphia, read a paper on "The Variation in Strength and Consequent Unreliability of the More Common Official Preparations of the *Materia Medica*, as Proven by Special Clinical Observations." He spoke of the variations in the composition, properties, etc., of the many drugs derived from plants which, on account of their wide differences and complexity of textures found in the same variety, explain the unreliability and the different results following the administration of what are regarded as standard medicines.

Dr. ADOLPH KOENIG of Pittsburg, spoke on "Therapeutic Fasting in Typhoid Fever." Where common sense dictates no food is demanded by a patient, none should be given. The feeding treatment is so engrafted upon the public mind, the profession have so long been told to feed up that it is difficult to introduce any innovation; still, the value of fasting in this

disease is gradually becoming known to both the public and the profession, and we find it less difficult to make patients agree to this plan. Benefit is produced by some medicines which act to prevent the accumulation of gases in the abdominal canal, to favor the ease and comfort of the patient, check diarrhea or other complications. He plead for a fair trial of this plan of treatment.

Dr. S. SOLIS COHEN of Philadelphia, read a paper on "The Management of Typhoid Fever." He spoke of the necessity of each case being studied separately. Each was a law unto itself. It was only by this careful investigation of each individual case that we are able to determine whether food is demanded and how it is to be administered. Small quantities of food are easily assimilated and generally prove of value. It is important that at least one quart of boiled water should be given in each twenty four hours. As to the bath, red wine is preferable to whisky before and after it is taken. After the twelfth day the plunge-bath should not be employed under any consideration. He detailed the various medicines needed in these cases.

Dr. A. A. ESHNER of Philadelphia, read a paper on "Orchitis Complicating Typhoid Fever."

Dr. McCORMICK of Williamsport discussed hemorrhages in this form of fever. He was very positive as to the objection to opium in this disease and the necessity of maintaining an open condition of the bowels. Quite an animated discussion followed, participated in by many of the members.

Dr. McCONNELL reiterated his views as to food in the disease and quoted a case of a lady who lived seventeen days without taking a particle of food and made a splendid recovery. He gave nothing but water to his patients at intervals of two hours, and only when hunger was complained of by the patient did he give food. The consensus of opinion was that more depended upon care, water, food only when absolutely needed, than upon any form of medication.

Dr. W. T. ENGLISH of Pittsburg read a paper on "Opiates in Treatment of Bronchitis." Among the valuable results obtained was the reduction of irritation, alteration as to the amount of secretion, removal of sleeplessness; and he claimed a speedy cure of the case to follow this plan. He preferred opium in the form of Dover's powder and preferably at bedtime.

Dr. H. A. HARE of Philadelphia, gave his "Treatment of Toxemia by Intravenous Injections and Hypodermoclysis; of Aneurysm by Electrolysis; of Hemorrhage by Calcium Chlorid." In each instance he gave the history of cases which he had successfully treated.

Papers on "Precocious Locomotor Ataxia and the Argyll-Robertson Symptoms," by Dr. F. S. PEARCE of Philadelphia, and "Notes and Observations in Purulent Pleurisy," by Dr. WESLEY S. STRICK of Glenville, were read, followed by Dr. J. MADISON TAYLOR of Philadelphia, on "Three Cases of Lumbar Puncture in Infants, Affording Distinct Relief to the Symptoms of Lep-tomeningitis." He fully reviewed a number of cases of puncture of the spinal cord and the cases, three in number, where infants devoid of sight, hearing and speech, and suffering with meningeal symptoms, were restored. The operation is simple and devoid of danger under reasonable antiseptic precautions. He hoped the operation would soon come more thoroughly into use.

The "Address in Hygiene" was delivered by Dr. A. B. DUNNOR of Reading. He spoke of forestry restoration as of vast importance to the entire country, preventing floods, draughts etc., care as to prevention of fouling water by garbage purification, of drinking water, sewerage, attention to the mode of production of ice for domestic uses, the inspection of food products, the dangers of indiscriminate kissing, personal cleanliness, and similar topics relative to hygienic surroundings.

Dr. J. V. SNOEMAKER of Philadelphia, exhibited several cases of skin disease, detailed their clinical history, and showed a case of psoriasis superinduced by an attack of rheumatism, and another of fibroma molluscum where the body was covered with tumors, some of which the Doctor had succeeded in removing by electrolysis.

In the evening the semicentennial exercises were given in the Court House. Hon. W. U. HENSEL of Lancaster welcomed the society to the hearts and homes of the people of Lancaster and the County, and detailed at length the part that this county had taken in the organization of the State society. He alluded to the men of the past who belonged to Lancaster, the names of John L. Atlee, and others.

President W. M. WEIDMAN then delivered the Annual Address, which was a review of the past and the great part that the society had done in organizing the profession not only in the State but in the whole country; then he urged the need of the society taking a more active part in promoting legislation

for the profession, the making of the several sessions of the county societies more valuable in every way, and also suggested that the bulk of the work done could equally well be done by special committees, saving the time of the society for more valuable matters.

A letter from Dr. ALFRED STILLE of Philadelphia, one of the founders of the State society, was read, deploring the fact that failure of health prevented his more active participation in the work of this society, of which he was once the Secretary, though he had always taken a deep interest in all its doings.

SECOND DAY.

The second day's session began at 9 A.M. The Committee on Nominations was announced and then the scientific business began. The death of Dr. CHARLES R. EARLEY of Ridgway, Elk County, was announced. Dr. Earley was long a prominent member of the society, but within the last few years had not been able to be present owing to the infirmities of age.

Dr. D. H. BERGEY of Philadelphia read a paper on "Natural Agencies Concerned in the Purification of Polluted Waters." He covered the subject of the tendency of nature to, by her vegetable and mineral agencies in the waters, purify the polluted water found in nearly every stream. All sources of pollution should be prevented as far as possible, thus not making the task of nature too great. His explanation of the work done by the benign bacteria in their destruction of the dangerous elements which enter so largely into polluted water was lucid and convincing.

Dr. H. S. ANDERS of Philadelphia discussed

THE INDIVIDUAL COMMUNION CUP AND ITS CRITICS.

The agitation for this reform has been conducted in a scientific manner. The fallacy of some of the criticisms is now to be dealt with, then show that the innovation is sound, sensible, sanitary and sacred in conception and practice. It is not a "fad" or its progress would not have been so quiet and steady, its appreciation so positive and permanent. Some say it is unnecessary. This comes from the class who decry vaccination, antiseptics and other sanitary improvements. The dangers of the common cup have not been exaggerated. He wished to emphasize the fundamental principle of absolute cleanliness as the true and efficient reason for individual cups, since that was impossible in the saliva-tainted, tobacco-fouled, breath-blown, moustache dripped and sometimes disease-infected ordinary chalice. As to impracticability, the cups are practical and in constant use in over 300 churches in the United States. Inexpediency is a timid, politic excuse unworthy of any medical man professing to be instructed in matters pertaining to the public health. The conviction as to the principle involved is clear and strong. Why not have the courage of conviction in recommending and disseminating it? It is not always necessary to urge the adoption of individual cups, but the principle of cleanliness is never inexpedient to urge in relation to the communion, any more than to the home table. This movement is educational in method, not coercive. The criticism that the whole affair is unwarranted and sacrilegious interference is shown to be due to a misconception of the reason for the change: the form of administering communion wine only is changed, without trenching upon essential doctrine, creed or dogma, as was evidenced by the fact that all principal denominations, even in most orthodox churches, are using individual cups. That is believed to be no scriptural objection, since the wine, not the cup, is the essential element of ceremonial significance. Brief quotations from various denominational religious journals and the author's observation in being in close touch with the sanitary movement, controverted the criticism that the individual communion cup idea was subsiding and a failure. Marked progress has been shown to have taken place during the past year and many churches are now either about to adopt, or for financial reasons are only postponing to adopt, individual communion cups.

Drs. DILLER and MASSEY discussed the subject.

Dr. E. ROSENTHAL of Philadelphia read a paper entitled, "Remarks on Infant Feeding." He offered suggestions as to the preparation of cow's milk for use from the day of the infant's birth.

Dr. C. W. DULLES of Philadelphia detailed "The Simple and Satisfactory Method of Examining the Urine." In discussion, the majority appeared to regard the great need of the microscope in such examinations.

The "Address on Surgery" was read by Dr. W. L. ESTES of South Bethlehem, who mentioned some of the remarkable operations of recent years, especially the removal of the stomach by Dr. Schlatter, as a grand triumph, the patient being still alive. He expected the war would furnish much material for the skill of our surgeons.

Dr. C. K. LADD of Towanda followed on "Aseptic Surgery

in Country Houses," and gave at length the grand results obtained under such circumstances.

Dr. W. S. FORBES of Philadelphia read a paper on "Removal of Stone from the Bladder."

Dr. E. O. KANE of Kane read a paper on "Catgut" in its uses in connection with operations in surgery.

Dr. ERNEST LAPLACE of Philadelphia presented "The Pathology and Surgical Treatment of Chronic Varicose Ulcers of the Leg," and cited a number of cases which had been successfully treated at the hospitals in Philadelphia under his personal observation. He quoted these as a defense of his special manner of operating as had been detailed at a former meeting.

Dr. T. C. DETWILER of Lancaster in "Excision of the Thyroid Gland," reviewed the subject of goiter, and the method of treatment. He exhibited a case of a young man with a neck seventeen inches in circumference which could be increased to twenty-four inches.

Dr. B. ALEX. RANDALL of Philadelphia detailed "One Hundred more Mastoid Operations," in addition to a large number formerly detailed.

At the opening of the afternoon session, the Committee on Nominations reported: For president, W. B. Lowman, Johnstown; first vice president, R. B. Watson, Lock Haven; second vice president, G. W. Guthrie, Wilkesbarre; third vice-president, J. Aug. Ehler, Lancaster; fourth vice president, Henry Landis, Reading; secretary, C. L. Stevens, Athens; assistant secretary, G. W. Wagoner, Johnstown; treasurer, G. B. Dunmire, Philadelphia, and a number of delegates to the AMERICAN MEDICAL ASSOCIATION and to other societies, and the usual Censors, Board of Trustees, etc. These were declared the officers for the ensuing year.

Dr. J. R. CARE of Worcester read a paper on "Unilateral Castration and Effect on the Prostate Gland." Here the gland was enlarged, and the operation followed by complete cure.

Dr. S. BIRDSALL of Susquehanna read a paper on "Delayed Ossific Union in Fractures of the Leg." He had had quite an experience in such cases, especially in children, and went into some detail as to the proper means of keeping the bones in apposition and promoting ossific union, etc.

Dr. L. H. ADLER, Jr., of Philadelphia followed on "Technique of Rectal Examinations and Diagnosis."

Dr. W. M. BEACH of Pittsburg read a paper on "Chronic Diarrhea as a Symptom of Rectal Disease," and exhibited, in illustration of his paper, a number of instruments which he employed in the treatment.

"Some Cases of Rectal Surgery" was treated of by Dr. A. R. CRAIG of Columbia, speaking more particularly of hemorrhoids as the most important occurrence demanding our attention here.

Dr. J. L. HAMMOND of Philadelphia spoke on "Radical Cure of Hernia, by the method of Nélaton and of Ombradin."

The Board of Trustees reported and recommended the appropriation of \$2000 to the Rush Monument Fund to be held as a trust fund till the contract for the erection of the monument was accepted, then the sum of fifty cents was to be assessed upon each member of the various county societies in addition to the regular annual assessment, the year beginning January 1. Quite a discussion ensued on this and kindred topics, among others the way the journal was conducted, some appearing to oppose its continuance. It appeared as if a number of the members preferred the old method of issuing the proceedings annually in one volume, but after much discussion, the matter was decided in favor of the present method of publishing the papers and other transactions of the society.

Dr. G. B. MASSEY of Philadelphia read a paper on "Electro-Mercuric Treatment of Cancer," and detailed a number of cases so treated. He earnestly urged the efficiency of this method of treatment.

"The Pressing Demand for a Revision and Recast of Surgical Principles with the Birth of Some New Ones," was the subject of a paper by Dr. G. W. HIETT. He urged "horse sense" in place of the ancient theories as now developed by modern facts.

Dr. J. B. ROBERTS of Philadelphia presented a paper on "The Surgical Treatment of Common Deformities of the Face," advocating surgical operations for the correction of these deformities, and the repetition of operations till the best result has been obtained.

Dr. B. H. DETWILER of Williamsport delivered the Address in Mental Disorders. There are 10,000 insane cases in Pennsylvania, 800 not provided for. The annual increase is about 300. He regarded this as the result of the defective marriage laws. Like begets like, so when the defectives, the criminals, etc., are permitted to intermarry, the result is progeny of similar tendencies. This is not only for one but many generations. Law must stop this. We are entailing a curse on posterity.

Dr. J. CURWEN of Warren spoke on "Provision for the Insane in Hospitals especially Constructed for the Insane." He has long been connected with this matter and is perhaps one of the best experts as to the proper method of caring for these cases. He has been instrumental in having several hospitals for the insane built in Pennsylvania. He gave a very full history of the establishment of these hospitals in the State from the earliest inception to the present day.

"Hypnotism" was treated by Dr. G. E. BRILL of Harrisburg.

Dr. C. W. DULLES of Philadelphia again reported "On Hydrophobia." He stated that only six persons have died from this disease in Pennsylvania during the year past. Of 267 persons bitten, only 8 deaths have come to his notice.

Dr. T. C. DETWILER of Lancaster read a letter from the Pennsylvania University relating the manner of death of several rabbits inoculated with matter from cases supposed to be of persons afflicted with the disease. The subject was very fully discussed.

In the evening the members listened to the address of Dr. ROTHROCK on "Sanitary Relation of our Highlands to the State." He urged the vast importance of law to prevent the woodman's axe from destroying the wooded belt in the northern tier of counties. He believed forest land on high elevations is a positive cure for mild pulmonary tuberculosis. Another reason for preserving the woodlands is the protection of the water-supplies, regions becoming arid wastes solely by the destruction of the trees. The lecture was illustrated.

Franklin and Marshall College and the Seminary were thrown open to the visitors, who were hospitably entertained by the faculty and ladies, and every effort was made to show the appreciation of the visit of the Society to the City of Lancaster.

THIRD DAY.

On Thursday, the session was resumed, a number of valuable papers being read by members from all parts of the State. By the suggestion of Dr. L. J. Lautenbach of Philadelphia, a committee was appointed to investigate the text-books on physiology now used in the public schools, as some of these were misleading, even dangerous in their statements.

In the afternoon, papers were read by A. M. Fullerton of Philadelphia "Experiences in Gynecology"; by H. L. Williams of Philadelphia on "Primary Malignant Diseases of the Corpus Uteri and Value of the Microscope in an Early Diagnosis"; "Things which should be done or not done by the General Practitioner in Diseases of the Ear," by Ada Audenried of Philadelphia; "Nasal Catarrh and its Relation to Diseases of the Ear," by W. S. Brenholz of Lancaster, condemning the hot treatment so much in vogue and giving many arguments to prove the correctness of his views. He urged proper and thorough treatment of nasal diseases so as to prevent subsequent disease of the ear and objected to the nasal douches in the treatment.

Dr. L. J. LAUTENBACH of Philadelphia read a paper on "Rupture of the Drum of the Ear not Necessarily Incurable." He condemned the views so much held by the people, evidently due to improper teaching of the text-books.

Dr. THEODORE DILLER of Pittsburg read a paper on "Mental Hygiene of the Adolescent Period."

The Committee appointed on text-books on physiology, was Dr. Lautenbach of Philadelphia, Israel Cleaver of Reading, R. B. Watson of Lock Haven, O. F. Harvey of Wilkesbarre and John Fay of Altoona.

The installation of the President was then proceeded with, and after the usual thanks to the citizens, etc., the Society ended its semi-centennial session.

Illinois State Medical Society.

Abstract of the Proceedings of the Forty-eighth Annual Meeting, held at Galesburg, May 17, 18 and 19, 1898.

(Continued from page 1333.)

In the evening of the first day the Society met at the Auditorium. Dr. J. M. G. CARTER, the President, delivered his annual address,

ADVANCES IN THE DOMAIN OF PREVENTIVE MEDICINE.

The chief object of the address was to show that a responsibility, almost an emergency, existed in the field of preventive medicine, and that this responsibility rested upon the State. He did not expect to be able to present more than an outline of what seemed to him to be a partial possible solution of the problem. He presented the following propositions as expressing his ideas of what is required:

1. The State or municipality should give men who can not secure other work some kind of employment which will afford them a living.

2. This may be done by introducing such public improvements as will add to the comfort of the people or otherwise benefit them or enhance the value of property.

3. A minimum rate of wages should be paid so that only those who can not find work elsewhere would seek such employment.

4. All able-bodied men without work who have no visible means of support and who do not apply for such government employment should be subject to draft for this labor.

5. The unfortunate and disabled poor should be cared for as wards of the State. Religion, humanity and civilization demand this.

6. The State should see that the poor are properly or comfortably domiciled in houses provided with good ventilation, supplied with good water and sufficiently warm. If possible, houses should be furnished with bathrooms.

7. Inspection of the homes of all the people should be conducted regularly and thoroughly, whether in public or private houses. The object of this inspection being to see that they are in good sanitary condition.

8. All foods put upon the market, meats, vegetables, fruits, dairy products, milk, manufactured products, etc., should be inspected as to their source, composition and present condition.

9. Public baths should be established where the poor can have facilities for bathing free or at a nominal cost.

10. These provisions should be enforced under conditions which will not interfere with the freedom of a liberty-loving people.

These propositions were elaborated.

Dr. J. W. PETTIT of Ottawa delivered the Address of Section 3,

STATE CONTROL IN MEDICINE.

He detailed the progress of legislation in favor of stricter requirements for the licensing of medical students. The old diploma law was instanced. Reference was made to the movement for the passage of a bill raising the requirements for the practice of medicine. The bill in question provides that candidates for medical licenses shall be qualified in all the general principles of all systems and schools of medicine and shall be subjected to examination by a State board before they shall secure their licenses. This agitation can lead but to one end, the wiping out of sectional lines among medical systems. The Doctor outlined further the specific provisions of the proposed law. He noted its vast benefit to the public and the profession alike, and urged the physicians of the State to use their utmost efforts to influence members of the legislature to bring about the desired enactment.

In the absence of Dr. NICHOLAS SENN of Chicago, who was to have delivered the address on surgery, entitled "The Surgical Treatment of Intestinal Tuberculosis," the President introduced Dr. JOHN H. FINLEY of Knox College, who spoke upon

INTELLECTUAL BACTERIOLOGY.

He referred humorously to the micrococcus egotisticus, a germ which impelled one to look out for himself and get everything he can. The woolgathering microbe often afflicted students and brought about in them a revulsion to thoughts of labor. Another microbe was the bacillus bombasticus, and still another, the micrococcus oratoricus, found frequently in Knox College. The spirillum Americanum abounded largely in the blood of Admiral Dewey.

SECTION 3, ETIOLOGY, STATE MEDICINE AND MEDICAL JURISPRUDENCE.

Chairman, Dr. DANIEL R. BROWER of Chicago; Secretary, Dr. C. B. JOHNSON of Champaign.

The Chairman, Dr. BROWER, in his preliminary remarks on opening the Section stated that the present status of medical expert testimony was a great discredit to the learned professions. The courts in many States have declared it to be of no value, whereas physicians know that testimony that is expert is of incalculable value in a court of justice.

Relative to State sanitation, legislation was needed. The medical profession deserves special credit for its self-sacrificing determination to prevent disease.

The first paper in this section was read by Dr. GEORGE N. KREIDER of Springfield. At the outset, Dr. Kreider stated that no law passed by the State legislature would succeed in driving out the quacks who were practicing in the State. He offered suggestions regarding the position of the Board of Expert Examiners, the fees to be charged, the penalties to be imposed for violations of the statute if passed. The physicians

of Illinois required a good law on the statutes and should expend their utmost efforts to that end.

Dr. HAROLD N. MOYER of Chicago followed with remarks on "What Should Be the Law in This State?" He stated that a new restrictive law was particularly needed because a great number of quacks were practicing in the State under the protection of the present State license. The speaker sanctioned the clause in the proposed bill providing that each licensed physician register his name with the State every year.

Dr. L. R. RYAN of Galesburg spoke of the advantages of separating the State Board of Health from the Licensing Board. He defined the duties of the State Board of Health, which had now become so arduous, he said, that it could not attend to the additional duties of a licensing board.

Dr. BASCOM of Ottawa followed with remarks in which he spoke of drafting laws for Illinois upon the lines of those of other States. He promised the proposed bill, with its minor changes, the full support of the Illinois Homeopathic Medical Society.

Dr. J. O. DECOURCY of St. Libory gave a summary of the laws governing expert testimony in other States and countries.

DEFECTS OF LAWS GOVERNING EXPERT TESTIMONY IN ILLINOIS.

This paper was read by Dr. SANGER BROWN of Chicago. He drew attention to a feature which had in many instances excited more or less adverse comment from every one who had observed it. He referred to the spectacle afforded by the experts on one side appearing to directly contradict those on the opposite side. It is claimed that this happens because there is no efficient law to prevent any licensed physician whatever from posing as an expert where a medical question is involved. Further, that each side hiring its own experts, physicians so employed naturally take more or less of a partisan attitude upon the witness-stand, if indeed some do not lie very palpably. It is desirable that a course requiring instruction from an expert should avail itself of the services of the individual best qualified to render them, and also that he should sustain no relation to either litigant which might tend to render him in the least partial. Dr. Brown said that under the present lay an expert is usually allowed a fair opportunity to express his views on the case on trial, and if honest and competent, he need have no fear of cross examination; but if dishonest and incompetent, he is likely to fare badly and cast discredit upon the profession.

Dr. FRANK P. NORBURY of Jacksonville, also spoke on the subject of

DEFECTS OF LAWS GOVERNING EXPERT TESTIMONY IN ILLINOIS.

Expert testimony, he said, has been tossed ruthlessly on the wave of public opinion in recent years. Not that its value has been undervalued upon the whole, but rather that its practice has been considered too much of a barter and sell procedure. It has unfortunately fallen under the ban of commercialism, and the expert no longer represents to the public an untrammelled, unprejudiced witness, but stands in the light of having been committed to the tender rights and interests of the side for whom he is sworn, and by whom he is retained. He is supposed to represent the facts of his side in a way that will favorably sustain the opinions advanced by the counsel of the client and to construe these facts under oath. While this is the picture presented by the lay press to the people, and by them discussed, yet the courts, counsel and the profession find after all that expert testimony really has value and is essential to the administration of justice. The essential elements of value Dr. Norbury believes are based upon three factors, as expressed by Becker. 1. What is the own value of the expert, meaning his ability and honesty? 2. What are the established facts in the case upon which he bases his opinion? 3. What have been his opportunities for examination of these facts? Upon such a basis the courts recognize the true value of expert testimony, and in the general questions of science and skill, are disposed to give just weight and consideration to an expert opinion when expressed.

Dr. D. W. GRAHAM of Chicago, read a paper entitled

SUGGESTIONS FOR OUTLINES OF A LAW REGULATING EXPERT TESTIMONY.

He said that in the minds of those desiring legislation on the subject of expert testimony, there are two distinct things to be accomplished. One pertains to compensation of the expert witness, and the other looks toward some method of securing impartial testimony of such character as will command the confidence of all concerned. In outlining or framing a Bill that will in any degree accomplish this purpose and meet the approval of the majority of those most interested, there are several points to be considered. 1. The scope.—Should such a law be applicable to all kinds of expert testimony or only to medical? Should it be applicable in both civil and criminal trials?

Should it apply throughout the State or only in the larger counties, as, for instance, those having not less than a given number of inhabitants? So far as it is a constitutional question, he is assured by high legal authority that a law framed in accordance with either the affirmative or the negative of these propositions could not be construed as class or special legislation, such as is prohibited by the State Constitution. So far as the speaker's own judgment and information go, he believes it would be expedient to limit the application of such a Bill to medical testimony and make it apply both to civil and criminal cases throughout the State rather than to the larger counties. 2. The second point relates to qualifications. It seems desirable that the Bill should specify certain qualifications for the expert witness, such as a minimum of experience, special study, residence, etc., and if it were to be applicable only in the large cities it would be expedient also. The question of qualifications could be left almost wholly to the judge and counsel to determine by preliminary examination. 3. How and when appointed? The presiding judge in any case on trial involving medical testimony should be authorized in his discretion, or on the application of counsel for either party to appoint or subpoena one or more physicians as medical experts who shall be designated as court witnesses. The question arises whether the judge shall or may so appoint when either party to the suit applies to have court witnesses appointed. 4. The fourth point concerns what may be called the status of a court witness and his relation to other witnesses. He should be subject to the same rules as other expert witnesses and be examined and cross examined in the same manner, and the Bill should provide that the rights and privileges hitherto enjoyed by litigants should not be abridged in any degree by reason of the appointment of court witnesses. 5. Remuneration.—The fees provided for witnesses by the Bill should be moderate, and must be so, if it ever receives any consideration at the hands of lawmakers. Probably they should be fixed by the hour rather than by the day—say, not less than five dollars, nor more than ten dollars, for each hour actually in attendance.

Dr. Graham spoke of the recent decision of the Supreme Court in the Dixon case, saying that it made it the law that the expert witness is exactly on the same footing as other witnesses as regards fees and compulsory service in both civil and criminal cases.

Dr. DENSLOW LEWIS of Chicago, related his personal experience with the Dixon decision. He referred to its salient points, as well as to the arguments of counsel and the factors which apparently influenced the Appellate and Supreme Courts in arriving at the decision.

Dr. J. A. EGAN of Springfield, contributed a paper entitled "Legislation Necessary to Promote Better Sanitation Throughout the State." The aid to progress in preventive medicine by better sanitation was alluded to and plans offered for such a division of labor by health officers that improved sanitation shall be secured.

The Society voted its unanimous approval of the Medical Bill to be presented to the State Legislature.

SECTION 2.—SURGERY, SURGICAL SPECIALITIES AND OBSTETRICS.

Chairman, Dr. J. L. WIGGINS of East St. Louis; *Secretary*, Dr. A. E. HALSTEAD of Chicago.

UREMIA IN THE PROCESS OF CHILD-BEARING.

A paper on this subject was read by Dr. HENRY F. LEWIS of Chicago.

Uremia was defined as a condition of the system resulting from the retention in the blood of toxic products which should normally be eliminated, chiefly in the urine. Eclampsia is a frequent sequel of uremic phenomena occurring in the course of the child bearing process. In the consideration of the subject the author included the eclampsias, neuroses, psychoses, and other symptoms due to the toxemia accompanying or following pregnancy. The subject also included the albuminuria of pregnancy, which is found in a considerable proportion of all cases; the cases exhibiting the more serious symptoms of uremia without eclampsia; the cases where the toxemia causes convulsions, as well as the cases, few in number, where eclampsia comes on without albuminuria or other sign of urinary disturbance. Albuminuria occurs in about 5 per cent. of pregnant women. In most cases there is no important kidney lesion, and the albumin is due to a disturbed blood pressure or to hyperalbuminosis of the blood. Primipara are three times as liable to eclampsia as multipara.

Dr. HENRY T. BYFORD of Chicago, read a paper entitled AN IMPROVEMENT IN THE TECHNIQUE OF THE AFTER-TREATMENT OF PERITONEAL SECTION.

The day before a peritoneal section the patient is dieted and purged sufficiently to reduce the gaseous distention of the in-

testinal coils, to the end that they may be kept out of the way during the operation. In vaginal sections, and in abdominal sections for large tumors, the intestines are not so liable to be in the way as in abdominal sections upon small pelvic growths or diseased organs. In the latter class of cases the speaker tries to produce six or eight largestools the day before the operation is performed. Patients of relaxed fiber receive full doses of strychnin from the time he sees them. Two hours before the time set for the operation a mild but efficient cathartic is given, such as two teaspoonsful of the fluid extract of cascara. As soon as the patient awakes from the anesthetic, a dram of sulphate of magnesia in an ounce of water, or an equivalent dose of some mineral water, or an ounce and a half of the liquid citrate of magnesia is given every hour and repeated immediately whenever vomited. About six hours after the operation is completed a stimulating enema is given, consisting usually of two ounces of glycerin and four of water, or from half to a dram of inspissated ox-gall in half a pint of water (without glycerin), is thrown into the upper rectum, and repeated every two or three hours until flatus passes freely between enemata. When this occurs the saline is also stopped, but not until then. In trying to start the passage of gas most surgeons think it enough if gas and feces come with the enema. But this is not sufficient. The treatment must be continued until flatus passes freely between enemata, and if it ceases to pass occasionally after the enemata have been discontinued, then another should be given. If the operation has been a simple one, Dr. Byford commences the salines and enemata a little later, not to prevent bad results, but because the patient is usually very uncomfortable until flatus passes freely and is nearly always perfectly comfortable afterward. It enables him to do without morphin. On the other hand, if raw intestinal surfaces are left after a difficult operation, he sometimes gives a high glycerin enema before the patient is taken off the operating table. As presumptive proof of the value of this treatment, he has recently had 105 consecutive recoveries after peritoneal sections, and he commenced to be thus thorough and prompt in its administration about the time this series commenced.

Dr. FRANKLIN H. MARTIN of Chicago, read a paper on

OPERATIVE TREATMENT OF CARCINOMA UTERI,

in which he summarized thus: 1. A microscopic examination of the tissue of the three portions of the uterus should be made whenever one of the well known classic symptoms of carcinoma appears. 2. Carcinoma of the vaginal portion of the cervix should be treated by vaginal hysterectomy, including the upper portion of the vagina and as much of the base of the broad ligament as it is possible to include, with the ureters pushed well to the side of the pelvis. 3. Carcinoma of the body of the cervix should be treated by vagino-abdominal hysterectomy, with thorough removal of the broad ligament and the deep iliac glands. 4. Carcinoma of the body of the uterus should be treated by thorough removal of the uterus by vagina or abdomen so as to include the tubes and ovaries. The iliac glands should be removed if involved. 5. Neglected carcinoma should never be abandoned, but should be symptomatically relieved by curettage and cauterization, if the more radical procedure no longer seems practicable, with the possible hope of permanent relief in a small percentage of cases.

Dr. ROBERT H. BABCOCK of Chicago, spoke on the diagnosis of acute pulmonary abscess and gangrene, with especial reference to their surgical treatment.

Dr. HENRY P. NEWMAN of Chicago, read a paper on CONSERVATION OF TISSUE AND FUNCTION IN PELVIC SURGERY.

The object of the paper was to stimulate investigation along the line of greater conservatism of the general health of women. This may be aided: 1. By a deeper study into the problems of cell nutrition and general metabolism, in order to determine the relative value of glandular and other structures, and the relation of the pelvic organs to the great systemic laws. 2. By seeking the habits and regimen of individual patients as to diet, dress, social and educational life, etc., for the causes of disease, remembering that these, if allowed to go uncorrected, may handicap the best efforts of medical science, and effectually undo all that may be accomplished. 3. By giving to every definitely diseased structure the best opportunity to recover its function that science can devise, by prophylactic supervision of life and habits. By palliative treatment when it offers relief, and by prompt resort to surgical interference when it is called for in the interests of true conservatism.

Dr. L. L. MCARTHUR of Chicago, read a paper on "Sacro-iliac Disease (Tubercular)," in which he reported six cases. The speaker's aim in selecting this subject for discussion was to present what practical points he had gleaned from personal experience with five advanced cases and a sixth possibly incip-

ient case (all tubercular), as well as to call attention to a disease which must be thought of in making a diagnosis in every suspected hip-joint disease, sciatic or low lying Pott's, and which once seen will probably remain indelibly fixed in memory.

Dr. WELLER VAN HOOK of Chicago, described a new device for facilitating operations about the anus. Starting from the proposition that existing technical methods fail to provide means of aseptic or even approximately aseptic operating, especially in view of Cohn's demonstration of the penetrability of fresh cautery-eschars by pathogenic micro organisms, he reasoned that we should seek means of operating upon hemorrhoids and other anal lesions by dissection and suture.

The device consists of a half inch rubber drainage-tube, perforated near one end, and drawn through a minute opening in a piece of medium weight dentist's rubber dam tissue twelve inches square. It is essential to success that the bowels be prepared beforehand. The method recommended is: 1, laxatives to thoroughly evacuate the bowels, on one occasion only, four or five days before the operation; 2, daily colonic flushings thereafter; 3, after the laxatives have acted, one or two drachms of bismuth subnitrate daily in divided doses to keep the colon empty. In operating, e.g., upon hemorrhoids, the following technique is employed: The sphincters are stretched, the rectum irrigated and the tube with its covering introduced by means of an eight inch forceps. To keep the umbrella like device from slipping out and to keep the dam in contact with the rectal wall, some strips of gauze are pushed up into it, between the tube and the dam. The dam is then pushed aside, the tissues washed again with antiseptics and the hemorrhoids excised and the wound sutured. A piece of iodoform gauze saturated with compound tincture of benzoin is then inserted between the dam and the anal wall. The apparatus and dressing are left undisturbed for four or five days.

THE TREATMENT OF ACUTE ABSCESS AND GANGRENE OF THE LUNG.

Dr. E. A. HALSTEAD of Chicago, read a paper on this subject, in which he said that it was only within the last few years that well known surgical principles had been applied to intrathoracic suppurative conditions. The term abscess of the lung was employed in the paper to designate only acute suppurative inflammation, non gangrenous, which had its seat within the lung tissue, therefore cavities filled with pus formed either by a dilated bronchial tube or by destruction of lung tissue from tubercular infection were not considered. The most frequent cause of acute abscess of the lung was lobar pneumonia. Foreign bodies in the bronchi and penetrating wounds of the chest were occasionally the origin of pulmonary abscess. A pulmonary abscess varies in size, from that of a millet seed to one containing a quart or more of pus. As to the prognosis, fully 75 per cent. of the cases of gangrene of the lung terminated fatally if left to themselves. Patients with these conditions should be treated by prompt operative measures. The surgical treatment of the lung abscess comprehended puncture of the abscess, aspiration, incision of the lung and drainage. Puncture should only be employed for diagnostic purposes. Dr. Halstead then dwelt at length upon the technique of the operation of pneumotomy for abscess or gangrene, which he said varies according to the exigencies of the individual case.

Dr. A. C. CORR of Carlinville, contributed a paper entitled "Points in Minor Surgery." He first discussed shock and allied conditions, and then passed on to the consideration of stitch infection, burns, ingrowing toe-nails, and infantile phimosis. These subjects were taken up consecutively, and their treatment outlined.

Dr. J. O. DECOURCY of St. Libory followed with a contribution entitled "Straits of Early Life." He said that nothing could be more important to the obstetrician than thorough preparations to meet emergencies and difficulties constantly arising in the lying-in room. The speaker would have his clientage know something of the potency of preventive medicine, in the line of physical development, dietetics, climatology, sanitary or hygienic law; something of right from wrong mating and marriage, and the laws governing progeny in the transmission of traits which affect the mind and body of the offspring, either for good or for evil. In connection with the paper the author exhibited plates from Moreau and other authors, arranged by Getchell in his "Science and Practice of Obstetrics."

AN INTERESTING CASE OF PYONEPHROSIS,

was the title of a paper by Dr. A. I. BOUFFLEUR of Chicago. The points of special interest in the case were: 1. The history would naturally lead one to believe that the disease had existed

for practically three years without any interruption, but with a gradual increase in the number and severity of the symptoms. 2. Its chronicity and symptomatology with reported favorable effect of the salicylates would indicate the presence of lithemia with the probability of lithiasis. 3. The history indicates the occurrence of a pyogenic infection of a mild type at least one year before, as evidenced by the occurrence of sweats with malaise and a gradually increasing sense of weakness. 4. The development of pronounced evidences of sepsis probably marked the beginning of incomplete evacuation of the pyelonephritic abscess. 5. The persistent temperature and severe spasmodic cough were undoubtedly caused by the pyelonephritis with subsequent suppuration and a diminution of the cough, but with an increase in the evidences of general sepsis. 6. In the absence of any suppurative inflammation in the urinary tract Dr. Bouffleur concludes that the infection of the kidney came through the circulatory channel. While the source of such an infection is not infrequently indeterminable, he believes it can be safely concluded that the primary cause was the pneumonia or possibly a mixed streptococcus infection which complicated the measles. Such infections are prone to be of a mild character and metastatic manifestations may not appear for months after the primary affection.

Dr. JACOB FRANK of Chicago read an interesting paper entitled

PATHOLOGIC HISTOLOGY OF INTESTINAL UNION AFTER THE USE OF THE FRANK BONE COUPLER.

From the microscopic study of the healing of intestinal wounds after some of the various suture methods and mechanical devices, Dr. Frank arrives at the following conclusions: 1. That no suture method insures an exact coaptation of the various layers. The Czerny-Lembert suture, considered one of the best of the many suture methods, does not insure a perfect line of apposition. Frey, Wölfer's assistant, is of the same opinion. In a specimen three weeks after operation, after the Czerny-Lembert suture had been used, there was a marked turning in of the ends of the bowel. The mucosa in this specimen is not yet regenerated (here the speaker showed a chart). 2. In regard to the invagination suture method, he referred to but one very briefly, namely, that of Harris, which will stand as a type for the others. Union takes place, but the different layers are not in juxtaposition and the lumen of the bowel is greatly encroached upon. This is not only visible microscopically but macroscopically. The microscopic specimen was obtained sixty days after operation from a dog operated on by Dr. Harris himself. 3. That all suture methods leave the subsequent lumen of the bowel more stenosed than either the Murphy button or the author's coupler.

Referring to the different layers after the use of either the Murphy button or the Frank coupler, the speaker notes the following: That the mucosa regenerates completely and that it shows an entropion which is due to the contraction of the underlying scar. Boari, in his experiments with the modified Murphy button, claims that there is no regeneration of the mucosa. Murphy, in his experimental work, finds a complete regeneration of the mucosa. The muscularis mucosae is lost in the scar tissue. The submucosa blends with the cicatrix and presents no change from the normal.

Muscularis.—Neither the inner circular nor the outer longitudinal fibers show any regenerative process. Dr. Hektoen, in his report on Dr. Murphy's button operation sections, states that after thirty days the longitudinal muscular coat can be said to be almost restored and the transverse muscular completely united by connective tissue. In describing the section, which was removed after sixty days, Dr. Hektoen says that the longitudinal and circular muscular layers are continuous and not distinguishable from those in the normal intestine, except that they contain some small spaces (blood vessels) and occasional traces of fibrous tissue. Dr. Frank differs with Dr. Hektoen in that he has not found this condition in any of his specimens, nor in that made with the Murphy button on a dog killed sixty days after operation. The most conspicuous part of the scar is the non-regeneration of the muscular coats, and it is the feature which at once attracts one's notice upon looking at the section through the microscope. Dr. Hektoen further says that "were it not for the thickening described in the submucosa and muscularis mucosae it would be difficult, if not impossible, to recognize the line of union. The submucosa beyond question is thickened, but not so much so as to make it a prominent feature. This layer is regenerated, and as for the muscularis mucosae, it, like the muscular coats, has not regenerated." Dr. Frank does not question that some muscular fibers may grow out into the scar and meet, but they are not sufficient in number to call the process a regeneration. This is not found in any of his (Murphy's) specimens and suture

methods made by himself. The cutting of the muscular coat acts as a stimulus and the result is a proliferation in the cut ends, but the connective tissue grows far too rapidly to permit a regeneration.

Serosa.—This layer is invariably united perfectly and is closely applied to the muscularis. Owing to the irritation and reaction resulting therefrom it is considerably thickened and more vascular but otherwise presents no change.

The scar.—The fibers of the cicatricial tissue run from the serosa to the muscular coat. The direction of the fibers has an important bearing upon the subsequent narrowing of the lumen of the bowel. The fact that the fibers run from the serosa to the muscularis, tends to increase the lumen of the bowel when contraction takes place by lessening the thickness of the intestinal walls themselves. If the fibers took a circular direction a pathologic stenosis would ensue upon contraction.

Dr. H. C. FAIRBROTHER of East St. Louis spoke on the repair of bones.

Dr. JOSEPH B. BACON of Chicago read

A PLEA FOR EARLY OPERATION FOR LACERATIONS OF THE CERVIX UTERI.

He said that lacerations of the cervix uteri have been recognized and their resulting pathologic consequences scientifically noted only since about 1862. Emmet was the first gynecologist to recognize the fact that these lacerations were the cause of erosions, eversion, etc., that had previous to his discovery been treated and described as ulcerations of the neck of the womb. All were agreed that the Emmet as well as the Schroeder operation, in selected cases, was all that could be desired; but, unfortunately, there was quite a percentage of cases that neither the Emmet nor the Schroeder operation could cure. Dr. Bacon described a new adaptation of pathologic facts as recognized in the disease affecting non-striped muscles and fibrous tissues in other organs, and showed how like conditions may help to cause some of the serious results found in neglected cases of severe lacerations of the cervix. He claims that the destructive changes found in both fibrous and muscular tissue of the cervix, and later in the body of the uterus, are due to the persistent chronic inflammation and that these changes could be avoided or arrested by an early operation. But if neglected, there is no limit to the destruction and in time no operative procedure will more than relieve a part of the symptoms and can not remove the diseased tissue and cure the woman. He claims that the same pathologic laws that explain cicatricial strictures of the rectum, as advocated by Harrison Cripps, apply equally well to the cicatricial changes that are found in the cervix uteri because there is a like anatomic make-up of the muscles, glands and excessive fibrous tissue normally present in both: 1. The tendency of fibrous tissue, subjected to chronic inflammation, to become both hypertrophied and contracted. 2. The tendency of muscular fiber, when subjected to undue and persistent nerve irritation, to undergo fibroid degeneration with permanent atrophic contraction of its fibrous elements.

Dr. EMIL RIES of Chicago gave an interesting talk on plastic operations on the tubes, illustrating his remarks by diagrammatic sketches.

Dr. ELIZA H. ROOT of Chicago read an instructive and interesting paper on hydramnios and its effect on gestation.

Dr. EDWARD H. OCHSNER of Chicago read a paper on

THE TREATMENT OF SEPTIC INFECTIONS FOLLOWING PIN-PRICKS, ABRASIONS AND SIMILAR INJURIES,

in which a clinical distinction was made between four kinds of infections following these injuries. Under class 1 he considered a form of infection which betrays itself by a marked local disturbance with the formation of pus at the point of infection, the systematic disturbance being relatively slight. Under class 2, he spoke of that form in which there is marked local disturbance with the formation of pus at the point of infection and with an ascending cellulitis, the systemic disturbance being usually more marked than in class 1. Class 3 is that variety in which there is only disturbance locally, but in which there is an early and severe involvement of the regional lymph glands and severe general disturbance. Under class 4 he considered that form in which there is no demonstrable local disturbance and only relatively little disturbance in the regional lymph glands, but in which there is severe general intoxication due to the presence of pathogenic bacteria or their ptomaines in the blood. The treatment for these infections were dwelt upon at considerable length.

Dr. J. E. BEST of Arlington Heights contributed a paper on

THE RELATION OF MIDDLE EAR DISEASE TO FACIAL SPASM.

He had seen a few cases with the following history: After

severe exertion and exposure the patient complains of pain in the ear. This is followed in a few days by a discharge of pus, more or less profuse, from the aural cavity. Simultaneous with this or a few days later, facial spasm may occur. The author then dwelt upon the pathology. The etiology was purely of germ origin.

Treatment.—First treat the ear aseptically with peroxid of hydrogen, keeping it perfectly aseptic until all external trouble has healed. Allay pain during acute stage with morphia or other anodyne, used hypodermically if need be. Later, facial spasm may be relieved by ten grains of phenacetin, two, three or four times a day as required. This has given more relief than any other drug he has tried. If the case is of long standing or very obstinate, much benefit may be derived from the application of the electro-cautery applied to the nasal mucous membrane as nearly as possible over the site of the above-named ganglion. Repeat once in five or six days after thoroughly cocaineizing the mucous membrane.

The election of officers resulted as follows: President, T. J. Pitner, Jacksonville; first vice-president, H. N. Moyer, Chicago; second vice-president, J. T. McAnally, Carbondale; permanent secretary, Edmund W. Weiss, Ottawa; assistant secretary, W. F. Grinstead, Cairo; treasurer, George N. Kreider, Springfield. Place of meeting, Cairo, the third Tuesday in May, 1898.

Chicago Academy of Medicine.

Regular Meeting, March 18, 1898.

(Continued from page 1357.)

TUBERCULOSIS OF THE OCULAR STRUCTURES.

Dr. CASEY A. WOOD—So far as the eye is concerned, tubercular diseases affect it with comparative rarity if we except the lids. The ocular apparatus may be regarded as an organ practically shut off from tuberculous infection. Even the conjunctiva is probably a less frequent seat of tuberculosis than any other mucous membrane in the body. I need not say much about the palpebral skin which becomes tuberculous (lupus, lupoid, etc.) about as often as any other part of the dermal covering of the face. Tuberculosis of the conjunctiva is often unrecognized owing to its close resemblance, in the early stages, to trachoma. I have seen a few cases that were undoubtedly tubercular, but I think the diagnosis is easy. The proof of its presence lies in a bacteriologic and histologic examination of the suspected tissues. The later ravages of the disease are unmistakable, or at least give rise to the suspicion that the process in question is not purely trachomatous. The treatment is practically that of tuberculosis of the skin, thorough destruction of the diseased parts. I believe that a general tuberculosis may be set up as a result of systemic infection through the lymph channels communicating with the pre-auricular glands.

Infection of the cornea is usually secondary to conjunctival tuberculosis, and when it occurs may for a time resemble an ordinary pannus or an interstitial keratitis.

Tubercle of the intra-ocular structure is still rarer. The chief sites are the iris and choroid, and when they occur they are usually late manifestations of a general tuberculosis. The nodules of a tubercular iris usually appear upon an otherwise healthy membrane, that is apart from acute inflammation, so that one's suspicion of the true nature of the small growths should at once be aroused by the fact. Some of these cases recur with more or less damaged vision, if the patient lives long enough, but in the majority of instances the eye is destroyed.

I have seen very few cases of true miliary tubercle of the choroid, the commonest form of the disease, but this manifestation of a tuberculosis does not differ in any material effect from similar deposits elsewhere in the body. As in the lung, the giant cells may be pigmented and the minute nodules are not always discoverable by the ophthalmoscope. Probably the ophthalmologist would know more about the tuberculous choroidea if the disease developed itself in the early rather than in the late stage of a general infection; the patient becomes moribund before vision is much affected.

TUBERCULAR MENINGITIS.

Dr. DANIEL R. BROWER—The diagnosis of meningitis as a general proposition is easy, but the differentiation of the various forms of meningitis from each other is attended with the extremest difficulty. I am of the opinion that the ordinary differential points of tubercular meningitis at the bedside are of no value. Unless we can find the source of tuberculous infection in the individual, in viscera or in glands, unless the patient has previously suffered from tuberculous manifestations, or unless we can find tubercles in the choroid, or better

than all, the Skeer sign of tuberculosis, we have no proper basis on which to make a differentiation at the bedside. The Skeer sign, first described by the late Dr. John D. Skeer of this city, is situated on the inner pupillary margin of the iris, about one-sixteenth of an inch from the margin, as a distinct wreath of white clouds, doubtless due to tubercular deposits, and as the disease progresses and the contracted pupils become dilated, instead of the white cloud-like masses we have yellowish-brown circle, undoubtedly due to degeneration of the blood vessels in consequence of the presence of miliary tubercular deposits. And as the third stage progresses and the pupils become more dilated this yellow-brownish circle becomes very much attenuated.

The procedure proposed by Quincke of Kiel to puncture the subarachnoid space with a hypodermic needle, between the fourth and fifth lumbar vertebrae, and the microscopic and bacteriologic examination of the withdrawn fluid will determine the presence of the specific organisms that have produced the infection, and if it is tubercular meningitis, the tubercle bacilli should be found there. Indeed, the subject of the diagnosis and classification of meningitis should be rewritten, and in every instance we should determine by this simple procedure what the organism is, whether it be the diplococcus of pneumonia, the streptococcus or the staphylococcus, or whatever specific micro-organism may be the cause of the infection, and then with the nature of the infection known we will be in a better position to prescribe treatment and to make the prognosis. The prognosis in tubercular meningitis is absolutely bad and I think those cases of recovery reported are cases in which an error in diagnosis is made. They were not tubercle bacilli, but some one of the numerous other infections that may be produced. Sometimes they are so much alike that it is, as a rule, impossible to differentiate them at the bedside.

MENTAL PHASES OF TUBERCULOSIS.

Dr. HARRIET C. B. ALEXANDER—The psychology of phthisis has long been analyzed by alienists who not only recognize *spes phthisica* as a common phenomenon and as an expression of exhaustion removing the checks on emotional mobility, but recognize likewise another symptom which underlies much of the difficulty in treating seemingly sane victims of pulmonary tuberculosis. This mental symptom which is exceedingly marked, so much so that it always arouses a suspicion of tuberculosis, as a complication of psychoses, at least, is suspicious. The general mental state of the phthisical is essentially that of the primary confusional lunatic plus emotional mobility. As Spitzka has remarked, there is usually altering depression, emotional mobility, intensification of the egotism common to invalids and a suspicious mental state. As I pointed out nearly a decade ago, this suspicious mental state underlies the refusal of, and changes in, medicinal treatment, if the patient be at home, and the refusal of food if the patient be in a hospital for the insane. The most prominent and decided symptom which appears in the insane, in the larval stage of the disease, is this suspicion. In them, for this reason, physical examination is often difficult, and cough, hectic fever, etc., are often absent.

Frequently it happens that a far advanced phthisis seemingly likely to lead to sudden death comes unexpectedly to a standstill, cough, hectic fever, etc., cease, but demonstrable decrease of the mental symptoms is followed by reappearance of the pulmonary. This alteration was long ago pointed out by Dr. Schroeder van der Kolk. It had been observed by Dr. James Macdonald in the case of Guiteau's uncle, who died in the Bloomingdale Insane Hospital.

According to Clouston, it is possible to predict tuberculosis from the mental symptoms. If these cases have been acute at first, the acute stage is of very short duration and passes rapidly into an irritable, excitable, sullen and suspicious state. There is a want of a fixity of purpose in the mental condition. The intellect at first is not so much obscured as there is great disinclination to exert it. There are occasional unaccountable little attacks of excitement, lasting only for a short time, unprovoked paroxysms of irritability and passion in a subdued form. There is a disinclination to enter into any kind of amusement or continuous work. If this be overcome there is no interest manifest in employment. If there be any one single tendency characteristic of these cases it is to be suspicious. In many cases this insanity commences insidiously and shows itself by an alteration of conduct and affections, an increased irritability and waywardness. There are fitful flashes of intellectual brightness.

The inter-influence of insanity and insane hospital hygiene combined are illustrated in the results of Dr. E. C. Bondurant of the Bryce Insane Hospital, Tuscaloosa, Ala. He found from the results of autopsy among the negroes, who are pecu-

arly prone to tuberculosis of a rapidly fatal type, that while more than one-half of the patients in the insane hospital suffer from tuberculosis, one-third of those who contract the disease make a good stand against it, either entirely recovering or living for a term of years without being injuriously affected by small though unhealed foci of tuberculosis or dying from some other cause in the course of a very mild and chronic form of the disease.

My own results in the Cook County Insane Hospital, and those of Kiernan in the Ward's Insane Hospital, tend to corroborate and emphasize these results of Dr. Bondurant. His observations were made chiefly among negroes, in whom, since the war, phthisis runs a rapidly fatal course, since it usually attacks organisms broken down by lues. The prognosis of phthisis therefore in the white insane would be much more favorable than even that indicated by Dr. Bondurant. The influence of phthisis on many forms of insanity is to introduce a suspicious element not hitherto present. The suspicious emotional mobility renders it difficult to allow these persons any great liberty on parole as they are liable to take offense without any possible occasion. In some cases the emotional depression produced by phthisis in the ordinary types of insanity may proceed as far as melancholia in the true sense of the term. In one case coming under my observation, the patient seemed to be a true case of melancholia with the facies, capillary circulation and emotional depression well marked. The patient had phthisis and had been deserted by her husband. She ran down rapidly and seemed almost moribund from dyspnea, but rallied under the effects of quibachio given in half dram doses every two hours. She seemed to rally also from her depression. The fancies and depression of melancholia disappeared, but a new type of insanity made its appearance. It was found on careful investigation that the patient had had systematized delusions of grandeur for several years before being suspected of any mental disorder and that therefore the melancholia was a complication of a pre-existing paranoia which had not been suspected.

TUBERCULOSIS MAMMÆ.

Dr. ALEXANDER H. FERGUSON—Tuberculosis of the mammary glands is, comparatively speaking, rarely met with. The paucity of its literature no doubt led Cornil and Ranvier ("Treatise on Histology") to state that "examples of tubercles in the breast are unknown." Cornil has since contributed to this subject. The older surgeons described cold abscesses and fistula of the mamma with such accuracy as to leave no doubt in the mind of the clinician that they were tubercular in character. Sir Astley Cooper spoke of a "scrofulous tumor of the breast," and Velpeau described tubercles in the skin over the breast, and three manifestations of tubercle in the breast. The next writer appears to have been Nélaton, in 1839 ("Thèse d'Aggrégation," 1839). Under the head of diagnosis, Berard paid attention to it ("Diagnostic des Tumeurs cancéreuses et tuberculeuses du Sein," Thèse de Paris). After this about forty years elapsed without anything appearing in literature except a short article by Koltz, in 1879 (*Archiv für Klinische Chirurgie*, Bd. xxv). In 1881 Dubar's monograph appeared on "Tubercules of the Mamma"; as did also one by Le Dentu (*Rev. de Chirurgie*, 1881, 1-27). This is all I have been able to find in the archives of medicine before Koch discovered the bacillus of tuberculosis in 1882. The next year, however, an instructive article made its appearance by Ohnacker (*Archiv für Klin. Chir.*, 1883, Bd. 28, p. 366). Billroth treats of it in his work on "Diseases of the Breast." Other writers could be mentioned, such as Durel, Dubare, Marchand, Mandry, Bender, Poirier, Hutchison and others, as having given some attention to this affection of the breasts soon afterward. The literature has been steadily but slowly increasing. Our most recent works on surgery give it a place among the diseases of the breast demanding surgical interference.

1894.—Sabrazes and Binaud (*Archiv. de Médecine exp. et d'Anatomie path.*, Paris, November, 1894), noted that the patients are predisposed to tuberculosis by hereditary antecedents. They claim that traumatism awakens the inactive bacilli of tuberculosis, which are then carried by leucocytes into the injured interstitial tissue of the gland, where a caseous abscess forms. Their observations and conclusions are supported by Florentine and Parieti (January, 1894, *Journal d'Hygiène*, Paris).

Powers (*Annals of Surgery*, Vol. xx, No. 2, 1894), in an able article revises the literature. He found thirty-five cases recorded, only one of which was a male; twenty-two out of the thirty-four females were married; twenty-one of the married had borne children; six of the twenty-one had suffered with inflammation of the breasts; and three had a non-suppurative inflammation. He reports a case operated upon by Bull nine years previously.

1895.—Warren ("Surgical Pathology," p. 583) calls attention to the thirty-four cases recently corrected by Roux, two being males. Both breasts were affected in two cases; ages were from 16 to 52; injury happened in three cases, and in twenty-four cases it was secondary. Warren also quotes Mandry's collection of forty cases: one a male; aged 17 to 62; majority developed after confinement, but in eight cases no children were born; it was in the right breast in seventeen cases and in the left in eight cases: lymphatic glands enlarged in seventeen cases and appeared to have been secondary. No glands were noticed in seven cases. In one of Warren's cases infection took place through the ducts.

Berrink (*Beiträge zur Klin. Chir.*, Tübingen, 1895) thinks that extension to the breast from surrounding tubercular tissue infected from without is a common source of the disease, and where this is excluded the hematologic mode of infection must take place.

Gaudier and Peraire (*Revue de Chir.*, September, 1895, Paris) made a study of three personal cases. They state that the tumor may be small, movable, and as a rule, painless; the nipple generally retracted, and enlargement of the axillary glands often precedes the tumor in the breast. They insist on the epithelial intra-acinous origin of the growth, but they never found the Koch bacillus in the ducts of the breasts.

Catellani (*Il policlinico*, Rome, January, 1895) reports two cases. In one case there were three separate tumors, varying in size from that of a walnut to a pigeon's egg. The axillary glands were enlarged. There was no history of tuberculosis and her general health was good. The tumors and glands were removed and the bacilli of tuberculosis found in them; but inoculation experiments were negative. A year after the operation both cases showed no local relapse or sign of tubercle elsewhere.

Piskacsek and W. Roux (*Klin. Chir.*, Vol. viii) described two forms, the confluent and the disseminated. They claim it is mostly secondary, being caused either by metastasis or by extension of tubercular process in adjacent parts. They advise, in the disseminated form, early amputation of the breast and removal of axillary glands in all cases.

E. Bender described two cases where he thought the infection was primarily due to cracked nipple.

Howitz (*Hosp. Tidende*, 1895) describes a typical case of tuberculosis of mamma. A young girl, aged 18 years, presented herself, complaining of several lumps in the right breast, about the size of a walnut, also of an ulcer in the lower border of the breast, which did not seem to yield to treatment. Family history.—Mother and two sisters died of tuberculosis; brother had enlarged glands of the neck. Personal history.—first noticed small lump on breast, very little pain. This lump later opened itself and the ulcer was the result. On examination of the breast it was found to be a mass of indurated nodules. The nipple was very much retracted; axillary glands very much enlarged. A diagnosis of tuberculosis of mamma was made. Operation.—The breast was totally extirpated and contents of the axilla removed; patient made an uneventful and rapid recovery. Microscopic examination confirmed diagnosis.

1897.—Charles Greene Cumston ("Intern. Clinics," Vol. iv, 6th series, 1897) reports a case in the surgical service of Dr. E. Kummer in Geneva, Switzerland, in which the gland was extirpated for tuberculosis and cured, and observed four years after extirpation. In this case the axillary glands became enlarged and tender first, and three weeks afterward a swelling appeared in the left breast, which soon formed an abscess that was opened by her physician. A second abscess formed above the nipple, which was also incised. A third abscess similar to the others made its appearance. Chronic fistula followed. The nipple was retracted, the whole gland smaller than normal, the scar brownish in color and depressed. The breast was lumpy and indurated.

Tuberculosis runs the same course in the breast as it does in the other soft structures of the body. The changes in the tissues do not deviate from the tubercular granuloma and gross lesions of the usual type. The same nodules, the similar infiltration, the cheesy degeneration and its liquefaction, the formation of sinuses which become chronic, the same tendency to lymphatic extension and general tubercular infection, and the low form of chronic inflammation, identify tuberculosis of the mamma with tuberculosis elsewhere. The age, the puerperal state and lactation of the patient predispose to tuberculosis of this gland, as does also a family and personal tubercular history.

The breast may be larger or smaller than normal and look natural or be perforated with fistulae. The skin may or may not be discolored over diseased areas. The nipple may or may not be retracted. Foci in the breast may be single or multiple,

but usually the disease becomes disseminated throughout the organ. The axillary glands may be primarily or secondarily enlarged and fistulous or may not be diseased at all. Pain is not an early symptom and tenderness develops with it in the late stages. The tumor develops slowly and is usually accidentally discovered by the patient. When fistulae form they have little tendency to heal. There appears to be a marked tendency to tuberculosis of the lungs when the breast is tubercular. The infection of the breast may be primary or secondary, usually primary. The prognosis of the breast is almost always bad, but for the individual good, if early extirpation is resorted to.

The origin of the disease may be through the lymphatics, the blood vessels or local abrasions or sores on the breast, such as cracked nipples. I have had occasion to extirpate the mammary gland twice for tubercular fistulae and abscesses. One, an Icelandic woman, about 32 years of age, of scrofulous appearance, had nodules appear in the breast in the upper and outer quadrant several weeks after having had sore nipples during lactation. These formed fistulous tracts through the skin and opened spontaneously, and the glands in the axilla were enlarged, all of which proved to be tubercular. A second case demanding extirpation was also fistulous from chronic abscesses which developed during lactation, in a woman 25 years of age, with a marked tubercular family history. Some of the abscesses had been lanced and two or three had opened spontaneously. The fistulae led to almost any part of the breast and communicated with another. The nipple was retracted. The glands in the axilla were not considered enlarged and were not explored. The number of cold abscesses of the breast and single chronic fistulae that I have treated I do not recollect. I recall two cases of secondary infection of the mammary gland in the male, both of which extended from tuberculosis of a rib, and both of which were extirpated while dealing with the diseased rib.

Diagnosis.—The clinical history of the case in many instances may be all-sufficient to establish the nature of the disease, especially in its later stages. The surgeon should use his microscope almost as often as he does the knife and examine the contents of all abscesses and sinuses as a routine practice. The early discovery of the bacilli of tuberculosis in an apparently innocent abscess of the breast will materially influence the line of treatment and save the patient much suffering and possibly general infection. Nearly all cases of chronic mastitis, chronic mammary abscess, mammary fistula and the chronic mastitis of lactation, most of them, are no doubt tubercular in character. Ordinary pyogenic infections have usually a sudden onset, acute inflammation follows and in the exudate pus cells and pyogenic cocci will usually be found. Syphilitic gummata in the breast may be easily mistaken for tuberculosis. The specific history and test treatment are of importance here. Carcinoma should always be kept in mind in this connection, and one must not be misled by a hard nodule, a retracted nipple and lymphatic nodes, for these are found in tuberculosis of this organ.

Mammary actinomycosis.—Mammary actinomycosis very closely resembles tuberculosis in some instances. Müller (*Münchener Med. Woch.*, Munich, Dec. 18, 1895) has presented a study of the ray fungus in the mammary gland. The cases of secondary infection are not of interest to us, but two cases were apparently of primary origin. First case: aged 35 years; lactation, one breast used, the other received a blow and a nodule appeared. This was incised and pus let out. The wound healed in two months. The breast hardened again and a sinus formed. She looked well. The glands in the axilla were not enlarged. The sinus in the tumor led to a cavity which contained characteristic granules. The fungus was found in sections from the breast that was removed with the tumor. The second case, a woman aged 25 years, received a blow on the breast. It pained her for some time, and several months later a tumor formed. It was lanced and soon healed, but six weeks later another tumor formed, occupying the outer half of the left breast. A sinus formed in it. A cough was present, but there were no signs of lung disease. Linseed meal poultices was applied at one time in both cases. The diagnosis lay between chronic mastitis with abscess and tuberculosis. The diseased tissue was removed and some months later sections were made of it and the ray fungus discovered. From a diagnostic standpoint, it may be important to remember that in these two cases of probable primary actinomycosis there was in both: 1. A blow on the breast. 2. An incision. 3. The application of linseed meal poultices.

Treatment.—The treatment is local. For tuberculosis of this organ, as elsewhere, it resists all therapeutic measures. Tuberculosis of the breast endangers the life of the patient, and the researches of Kolosenikow have established the danger

of infecting an infant suckling a tubercular breast. The great tendency to implication of the whole organ, in addition to the above considerations, clearly demands the removal of the diseased tissues, usually of the whole breast and axillary glands. Vigorous treatment of cracked and excoriated nipples infected with tuberculosis may prevent the spread of the infection in the early stages. Local foci opened, curetted and iodoform dressing assiduously carried out suffice in some cases.

(To be continued.)

PRAGTICAL NOTES.

Arterial Compression as an Anesthetic.—M. Jabony of France claims to have produced anesthesia for a few moments by compression of the carotid arteries. The absence of total loss of consciousness he claims to be sufficient for reducing a dislocation, making an incision or setting a fracture. The success, however, may be due to suggestion.

Return to an Old Method.—Dr. Laache in *Deu. Med. Woch.* (1898, No. 9), gives three cases of uremia in which venesection was employed with the happiest results. The quantity of blood withdrawn was from twelve to twenty ounces. In the days of Dr. Benjamin Rush, venesection unsuspectingly gained many triumphs in this class of cases, inasmuch as the first resort was had to it in all comatose and convulsive conditions. The received notion even in those days was that the method was eliminative.

A New Clinical Symptom of Scarlet Fever.—Meyers (*La Presse Médicale; Philadelphia Times and Register*) reports a series of cases at the Hôpital du Port d'Aubervilliers during 1897, in which he observed a slight paralysis of the upper extremities with frequently only numbness in the hands. At times instead of a numbness only a pricking sensation located in the palmar surfaces of the finger ends or in the palm of the hand was noted. This was rare in the feet, but if present was found at the same time in the hands. The duration of the sensation is variable and rarely before the scarlatinal eruption. The author states that he has never met this symptom in other eruptive diseases, in diphtheria, in erythema from drugs and notably in mercurial manifestations on the surfaces of the skin.

Foot Blisters heal rapidly without pain or inflammation if they are incised the whole length with a bistoury and emptied, then each lip raised with a sound and the cavity sprinkled with iodoform powder. The blister is then covered with a thin layer of cotton and a small piece of adhesive plaster applied outside. No inconvenience is felt in walking, even at once; the wound dries in a few hours and new epidermis soon forms. —*Semaine Méd.*, May 4.

Manifold Advantages of Oil in a Collyrium.—Prepared with water the effect is uncertain, the application inconvenient, as it causes considerable afflux of tears and spasm of the lids, and the sterilization is difficult. These difficulties are entirely obviated by using olive or peanut oil freed from fatty acids by washing with alcohol and then heated to 120 degrees C. for ten minutes. The basic alkaloids dissolve more readily in the oil than the salts; mix cold and keep in a cool place. Apply with a glass stirrer slightly flattened and curved at one end, which takes up the oil and deposits it much more effectively than the dropper or brush, while easy to sterilize and gentle in its touch. — B. Scrin, *Semaine Méd.*, May 4.

A Case of Suppurative Appendicitis.—Dr. Thomas H. Emory (*Medical Record*, May 21, 1898), before the Medical and Surgical Faculty of Maryland, reported the case. The patient was a colored man, 21 years old. The surroundings were most unhygienic. Recovery followed with only a small fecal fistula. The features were: 1. Absence of chills at any time. 2. A moderate range of temperature and the character of the pulse. 3. The seeming subsidence of the symptoms two or three days before the operation. 4. The apparent readiness of the abscess

to break, the walls being extremely pliable. 5. The absence of any tumor or fluctuation.

Ichthyol in Affections of the Eye.—M. Ebersson recommends ichthyol in the highest terms, especially for children, in treating trachoma, as it shortens materially the course of the disease and ensures complete recovery. It also heals rapidly all cases of catarrh of the conjunctiva with or without corneal complications. It is also a powerful agent in clearing up cicatricial formations in the cornea. He uses a 50 per cent. aqueous solution, to which a little glycerin is added, applied and left a minute or two. The *Klin. therap. Woch.* of May 1, contains his report of numerous observations during the last two years.

Further in Regard to Orthoform.—The parts become insensible to pain in five minutes after the application of orthoform, in a powder of 10 to 20 per cent. salve. This effect lasts for thirty hours on an average, sometimes for three to four days. It always checks the secretion more or less, which is especially valuable in flap transplantations. In one case 60 grams a week were applied without secondary results, proving its non-toxicity. The base is preferable, as the salt causes slight transient smarting. Orthoform only acts locally and has no effect upon sound tissues, hence is valuable in diagnosing ulceration in the stomach. — *Munch. med. Woch.*, 1897, 44, 46.

Significance of a Green Color in Intestinal Strangulation.—Bégoin, in discussing the different colors of strangulated bowel and their significance, says that he has been able to artificially produce shades of yellow, yellowish green, and olive in loops of human intestine by means of human bile obtained at autopsies, as well as by the bile of dogs; but that he has never been able to reproduce the Florentine bronze which he has seen in some fatal cases of obstruction. The practical outcome of his investigations he thus sums up: a. A clear green tint may exist without alteration of the intestinal wall. b. Yellow green, dark green, bottle green, and black green have a more sinister significance. They do not necessarily indicate the death of the tissues of the bowel, but the latter may occur with these colorations. At any rate it is desirable to use other methods to determine this point, such as irrigation with hot water or pricking of the intestine. c. The same precaution should be employed in the presence of that beautiful green color known as Florentine bronze. In the two cases under the observation of the author in which this color existed, there was gangrene of the gut; but the evidence is too limited to say that such is of necessity the case. — *Gazette Hebdomadaire de Méd. et Chir.*, January 27.

Soluble Metallic Silver in the Treatment of Infections.—B. Crédé of Dresden announces that he has been very successful in the treatment of pure and mixed staphylo- and streptococcus infections with his argentum colloidal, which dissolves almost perfectly in water and albuminous fluids, applied as a salve rubbed in, or taken internally in pills or solutions. It is also used for uterine pencils and rectal injections. In order to have the tests uniform he has only given his formula yet to one firm, Heyden of Radebeul, near Dresden, although later he intends to publish it generally. The extreme solubility of silver in this form is surprising, and also the fact that the addition of a little albumin protects it against the action of the acids of the stomach which would otherwise transform it into an insoluble salt. No secondary effects have been observed from its use in any form, even with months of treatment. Crédé's recommendation of itrol and actol (arg. citr. and lact.) as a prompt harmless disinfectant for septic and aseptic wounds, clean, ready and marvelously effective, has been confirmed by many physicians in various countries, he states, adding that he has received most favorable letters from thirty-eight (*vide JOURNAL*, xxvii, page 1160). He expects that the soluble silver treatment will be found even more effective in internal medication. — *Klin. therap. Woch.*, 1898, Nos. 14, 15.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
 No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 109 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JUNE 11, 1898.

TYPHOIDAL CHOLECYSTITIS AND CHOLELITHIASIS.

The subject of the formation of gall stones and their relation to the presence of microbes in the bile has attracted considerable attention of late, and has been made the subject of quite a number of experimental and other investigations.

It would seem that in typhoid fever, in which an infection of the bile with typhoid bacilli occurs so very frequently, the conditions necessary for the formation of gall stones upon, so to speak, a bacterial basis would be unusually favorable.

Suppurative inflammation of the gall bladder has long been recognized as one of the complications of typhoid bacilli. The first report of cholecystitis caused by invasion of the bacillus typhosus was made by GILBERT and GIRODE¹ in 1890, and since then a series of many observations concerning the relation of typhoid fever to infections of the gall bladder has been made. In 1891 BLACHSTEIN² noted the almost constant occurrence of the bacilli in the gall bladder in cases of experimental inoculation of typhoid bacilli in rabbits, and Professor WELCH³ has called attention to the presence of the micro-organisms in this situation in these animals a considerable length of time after the inoculation; thus, in one case the bacilli were found in the bile on the one hundred and twenty-eighth day after the inoculation and after having disappeared from every other organ of the body. Since then a routine bacteriologic examination of the bile in the fatal cases of typhoid fever in the Johns Hopkins Hospital has shown that in about 50 per cent. of

the cases a pure culture of typhoid bacilli can be obtained.³ These organisms are usually present without any apparent symptoms; a variety of changes may be caused by their invasion however, ranging from catarrhal inflammation to the formation of stone, to ulceration and perforation and its consequences. Thus various writers emphasize acute suppurative cholecystitis as a not unusual complication of a late stage of typhoid fever.

CUSHING³ calls attention to the fact that there is a distinct group of cases in which acute cholecystitis appears, not during the fever, but some months subsequently, and in all of these there have been found gall stones. BERNHEIM⁴ emphasizes the frequency of attacks of gall stones in typhoid fever, and DUFOUT⁶ was able to trace a history of typhoid fever, preceding the attacks of gall stone colic by a few months, in nineteen cases. A review of the cases of cholecystitis occurring in HALSTED's clinic in the Johns Hopkins Hospital shows that ten out of thirty-one cases of gall stones gave a previous history of typhoid, the interval varying from a few months to several years.

In 1890 WELCH demonstrated micro-organisms in the center of gall stones, and suggested that they might be the starting point in the precipitation of biliary salts. NICHOLS is quoted by CUSHING as having observed the early appearance of the bacillus of typhoid fever in the gall bladder after intravenous inoculation, and a distinct clumping of the organisms was observed in those animals which were later examined postmortem. Such observations show that a reaction similar to the agglutination of the organism by serum may take place in the course of their sojourn in the bile, and indicate that the clumps may form the starting point for the deposition of calcium bilirubin salts and thus become the origin of a stone, symptoms of which may occur after convalescence. The development of post-typhoidal cholecystitis may therefore, according to CUSHING, be summarized as follows:

1. The bacilli, during the course of typhoid fever, quite constantly enter the gall bladder.

2. The organisms remain vital in this fluid for quite a long time.

3. In the course of time the bacilli become clumped, an intravesical agglutinative reaction takes place.

4. These clumps may be presumed to form nuclei for the deposit of biliary salts, in accordance with the fact that micro-organisms are quite regularly demonstrated in the centers of recently formed stones.

5. Gall stones associated with long-lived infective agents may provoke inflammatory changes in the bladder at any subsequent period.

CUSHING was able to collect four cases of post-typhoidal cholecystitis with cholelithiasis in which the bacillus typhosus was cultivated from the bile at

⁴ Quoted by Cushing, loc. cit.

the operation. To these four cases he adds two additional ones. This sequence which he outlined does not seem to be necessarily limited to infection with the bacillus of typhoid fever. BLACHSTEIN⁵ refers to a similar clumping of bacilli in the bile of rabbits after inoculation with the colon bacillus. The colon bacillus occurs in the bile in many fatal cases of typhoid fever. GILBERT and FOURNIER⁶ divide biliary lithiasis into two groups, one due to the colon bacillus, by far the most common, and one due to typhoid bacilli. These writers, and MIGNOT,⁷ have succeeded in producing experimental cholelithiasis of these two types. CUSHING has operated on one of the cases of the colon group, two years after an attack of typhoid fever. In this case the gall bladder contained many small faceted stones, in the center of which were evenly staining bacilli. Cultures from the stones were negative. The bile also contained isolated clumps of the bacilli, which possessed the cultural characteristics of the colon bacillus. The blood of the patient gave a Widal reaction to typhoid in a dilution of one to thirty.

It is extraordinary, however, to find that cholecystitis with stone may be associated with the bacillus of typhoid fever in which there is no history of any febrile attack, and in which the infection of the gall bladder seems to be primary. CUSHING reports a case of this kind. The wide-spread occurrence of the bacillus typhosus is just being recognized. Owing to the occurrence of the serum reaction many cases are clinically diagnosed as typhoid infection which may have but few of the clinical symptoms, and which, at the autopsy, may have been free from the characteristic anatomical findings of typhoid fever. A study of CHIARI's summary of these forms of typhoid fever, an editorial abstract of which was printed in the JOURNAL recently, shows that he has no division under which one could class the cases, the only evident lesion of which is in one organ and which clinically never presented any indications of typhoid. In CUSHING's case of this kind, which concerns a woman 26 years old, there was found a greatly enlarged gall bladder, with recent adhesions about it, containing gall stones. The bacteriologic examination showed on the cover-slips a few organisms, rod-shaped and with rounded ends. A comparative series of cultures demonstrated the presence of a bacillus which had all the characteristics of the typhoid bacillus, together with the serum reaction, which was controlled by the use of undoubted typhoid bacilli; and the blood serum of a case of active typhoid fever produced a similar reaction with both these organisms, while the blood serum from a healthy adult produced no clumping in either case. CUSHING therefore concludes that the bacillus found in the

gall stones had the morphologic and cultural characters of the typhoid bacillus, and this conclusion, that it actually concerns the typhoid bacillus, is made practically positive by the occurrence of the Widal reaction with the serum from the patient and with the serum from a clinically typical case of typhoid fever.

In connection with this, reference may be made to a case reported by Dr. MILLER,⁸ in which the bacillus of typhoid fever was found in the gall bladder seven years after an attack of the disease. This case concerns a woman 37 years old, who, in 1891, had attacks of cholelithiasis and a little later a febrile disease which was regarded as typhoid fever. Following this fever, which lasted four weeks, came a remission of about four weeks, to be succeeded by another rise in temperature lasting about one month. There occurred subsequent attacks that resembled gall stone colic. At the time of admission into the hospital she had constant pain and tenderness over the gall bladder. The diagnosis of gall stones was made, and operation revealed the presence of calculi in the cystic duct, which were removed. A bacteriologic examination of the contents of the gall-bladder showed the presence of a micro-organism which proved to be the bacillus of typhoid fever, giving the typical Widal reaction. The serum from the patient also agglutinated a known typhoid organism rapidly at one to one-hundred dilution, the reaction resembling that of an acute attack rather than one of an attack of several years ago.

EXPANDING VS. EXPLOSIVE BULLETS IN WAR.

The tendency of modern civilization is to more humanitarian methods even in war, but at the most it is only a tendency. The edicts of the Geneva Convention, while they should have the force of law, are like other laws, full of holes and possibilities of evasion. In civilized warfare no doubt they are expected to be observed, but a state of war is more or less a suspension of all laws, international and otherwise, and it is not probable that in all cases and under all conditions the considerations of humanity, or even the dicta of an international convention, will overrule the passions of excited warriors. As the state of the participants approaches to barbarism, this neglect of the dictates of humanity will be the more prominent, and the comparatively recent behavior of the Japanese at Port Arthur is a case in point. After all that is said, it was not so very much worse than Badajoz or Ciudad Rodrigo a little less than a century ago, when the soldiers of a Christian nation were at fault. In our own times we have the deliberate starvation of non-combatants in Cuba by a power calling itself Christian *par excellence*, whatever others may call it. War is hell, as General SHERMAN called it, and even its mitigations

⁵ Loc. cit.

⁷ Quoted by Cushing, loc. cit.

⁸ Johns Hopkins Hospital Bulletin, 1898.

are not all perfectly and successfully humane, in their execution at least, in spite of good intentions.

Some time back the JOURNAL noticed editorially what was apparently a palpable evasion of the prohibition of the use of explosive small arm projectiles in war, namely the Dum Dum bullet in use in the British army, which it was stated was also about to be adopted in the Russian service. A prominent surgeon, basing himself upon the results of experiments on cadavers, has positively condemned this missile as being equivalent in action to explosive bullets, in a paper read before the German Surgical Congress. He finds that it "sets up" or mushrooms in its passage through the tissues so as to widely extend the laceration of the soft parts, rendering it infinitely more serious and fatal in its effects. That its origination in a war with fanatical tribes whose rushes could not be stopped with the full coated Lee-Metford bullet, was in a measure excusable, does not better the case if the same practice is to be introduced into civilized warfare, nor does the fact that it is a spreading or "setting up" projectile instead of an exploding one alter the question if the effects are practically the same.

An English army surgeon has in a recent issue of the *British Medical Journal* taken up the defense of the Dum Dum bullet against these charges, but his argument is hardly a valid one. He gives the history of the evolution of the English bullet from the time of the old smooth bore round ball used down to nearly the period of the Crimean war, through the various types of belted, conical and other forms of projectile to the modern small caliber steel or nickel coated missile. He also describes the genuine explosive bullet used in hunting large game, and makes it clear that at least one military projectile used in the past—that of the Snyder rifle—was practically one of this type, the air contained in its cavity acting on impact like an explosive.

The higher power of modern military rifles has made some more resistant material than lead essential to prevent stripping and obstruction to the rifling of the gun, and the long pointed projectiles are therefore covered externally with a steel or nickel coating. When this coating is intact the bullet is rarely changed in shape in passing through the tissues, and the wound is therefore small and free from detached particles of the missile. When, on the other hand, the lead center is exposed at the point, as in the Dum Dum bullet, and still more when its casing is also notched or slit at the point, it spreads and becomes distorted in the wound and the harder casing, instead of being a protection to the tissues, adds to the lacerating effect. The wound therefore instead of being a mere puncture, hardly larger at the exit of the bullet than at its entrance, is a lacerated one, constantly widening in its progress through the body. The principal difference between it and an explosive bullet would therefore seem to be that it tears its way through and

makes a wound of exit, instead of lodging in the tissues. This is a distinction with a difference, it is true, but it is not necessarily an important one; if the damage done to the organs is sufficiently serious it matters little whether it is extended to a wound of exit or not, and in any case there is liable to be lodgment of detached fragments of the missile.

The motive of the prohibition of explosive bullets was the especially extensive and dangerous character of the wounds produced by them, and if this same effect is brought about by other means, the spirit, if not the letter of the law, is certainly violated. It is, moreover, not a valid defense to the charges made against any appliance to say that there have been others still more objectionable. The air explosive Snyder bullet does not excuse the spreading and tearing Dum Dum projectile.

It is a fine point for military casuists to decide, how far a weapon can be allowed to be destructive without going beyond what ought to be permitted in civilized warfare. The principal object in modern warfare is to disable rather than to kill the enemy, and if modern small arms with all their advantages of long range, lightness of ammunition, etc., are not sufficiently disabling, some other methods and appliances will have to be adopted. But in no case would it seem excusable to evade in letter or spirit the humane restrictions that by international consent have been accepted as imperative in warfare between civilised peoples.

PURE WATER FOR TROOPS IN THE FIELD.

Boiling the water is a sure way of preventing infection by the water-supply. It is a custom among the old soldiers of our regular army, who have done much scouting duty in their western service, to fill their canteens, for the day's march, with weak coffee or tea, which for practical purposes is the boiled water recommended by their surgeons; but it is not to be expected that 200,000 volunteers, hastily enrolled and equipped, could be trusted to protect themselves from typhoid fever and other infections in this way. The addition of chemicals to the water with the intention of oxidizing putrescent organic matters has been suggested; but if the water is so impure as to require their use, the simpler and better way of dealing with it is to insist on its conversion into cold tea. The use of small portable filters, to be carried and used by the individual soldier, has been urged upon the military authorities. But such filters, if issued, might be thrown away as an unnecessary incumbrance, since raw troops can hardly be trusted with the purification of their water-supplies. The purification must be done for them. To this end apparatus of various kinds for distillation have been considered. These, of course, give a sterilized water, and as arrangements may be made for aerating the water as it drops from the condenser, the distillate may be palatable as well as whole-

some; but there are practical difficulties in the way of managing such an apparatus in field service. Processes involving sedimentation are too slow to be of any use in camp life, even when these processes are hastened and their efficiency promoted by the use of such precipitants or coagulants as alum, lime or ferric salts; and electrolytic methods require a subsequent sedimentation or filtration, for their action is not that of direct purification, but merely the introduction of the hydrate of iron or aluminum into the water as a coagulant from the decomposition of the metal in the plates used. For troops in the field, filtration, therefore, appears to be the only practical method of purification.

A filter is efficient as a sterilizing medium in proportion to the fineness of its pores. When the pores are so small that water will not pass through them except when considerable pressure is exercised, as in the Pasteur-Chamberland or the Berkefeld filter, the purification is proportioned to the amount of pressure required. But in practice a layer of impalpable particulate matter, removed from the water, gathers on the outside of the filtering bougies or cylinders, blocking up their pores and putting an end to the filtration until this layer has been brushed away. The finer the pores the sooner are they obstructed. The porous cylinder which will give a sterilized water can be kept in use only by frequent interruptions for cleaning, during which its integrity is endangered. This seems to put these filters out of consideration for field use although Dr. CHARLES SMART, who used one last year on his emergency ration march with the First U. S. Cavalry in Oklahoma, states that his experience with it demonstrated the possibility of carrying on field service a machine which would supply a pure water for company use and urged that a provision of this character should be made for troops in the field. (Surgeon-General's Report for the year ending June 30, 1897, page 160.) On the other hand, filters with pores so large as to permit a free flow of water through them are necessarily inefficient. Although they may remove all particulate matters visible to the eye and give a transparent and clear filtrate, they do not remove the germs of disease. Evidently such filters are of no value for the protection of the troops. It is claimed on behalf of some of these that the thickness of the layer of filtering medium offsets the large size of the pores; but efficient filtration could be obtained in this way only by increasing the thickness until the resistance to the passage of the water was as great as in the earthen-ware cylinder, in which case there would be no filtration unless pressure was brought to bear on the water. Surgeon-General STERNBERG has, however, combined the use of the fine-grained earthen-ware filter and a large-pored asbestos filter in such a way as to have a free flow of sterilized water. The asbestos filter, operating under a water pressure of five or six feet, is used to free the water from its grosser

particles, and the clear filtrate is then passed through the Berkefeld cylinder under piston pressure. On another page of this issue of the JOURNAL we print General STERNBERG's circular of instructions for the use of these filters that the troops may be supplied with not merely a clear but a germ-free water.

CORRESPONDENCE.

WAR CORRESPONDENCE.

* BY LIEUT.-COL. NICHOLAS SENN, U. S. VOLS.,

CHIEF SURGEON SIXTH ARMY CORPS.

The beating of the drum, the measured tread of an armed host are again heard throughout the land and have aroused the patriotic spirit of the American people. For a fifth time our nation is face to face with a war the gravity of which it is impossible to estimate at the present time. The first war brought us our liberty and independence; the second established our reputation on the sea; the third taught our Mexican neighbor respect for our country; the fourth saved the Union, and the fifth, which is now being waged, was provoked in the cause of humanity.

For centuries the beautiful neighboring island of Cuba has been in the greedy grasp of a foreign nation. The people to whom this gem of the ocean belongs have been downtrodden, tyrannized over and abused by the cold iron hand of an effete monarchy. The humane liberty-loving people of the United States have heard the cry of the oppressed starving Cubans for years, and have done all in their power, short of resort to the sword, to relieve their sufferings, but without avail. The ear of the proud, cowardly Spainard remained deaf to well-meant and most earnest appeals. The Chief Executive of the United States exhausted every resource to improve the condition of the native Cubans, the rightful owners of the unfortunate island, without bloodshed, but all his efforts were ignored and antagonized by the brutal oppressors.

War is always a great calamity, but when entered upon for the sake of humanity, for the relief of the oppressed, it becomes a weapon in the hand of the Almighty. The issue before us is a righteous one, and it is not difficult to foresee the ultimate result. Justice and humanity are on our side; corruption and oppression on the other. On our part the struggle is purely unselfish; on the other it is a desperate but vain attempt to ignore the claims of an enslaved people. Such are the conditions of the present war with Spain, at the same time our people will now and for all time come "Remember the Maine."

The war has begun, the deafening roar of cannon has been heard in different Spanish ports, the hero of Manila has planted the Stars and Stripes, the emblem of liberty and equality, on the shores of the distant Philippine Islands: there it will remain until the unhappy inhabitants breathe the bracing air of independence. No war was ever undertaken in which the government had such a firm and enthusiastic support from the mass of the people regardless of politics, religion, nationality and position in life.

The policy laid out, advised and carried in effect by President McKinley, meets with the undivided support of the reunited nation. The gray is eager and anxious to don the blue in his country's cause. Federal and Confederate meet again to talk over the memories of the past at a common camp fire during the campaign against a common foe, who has been permitted far too long a time to abstract the life blood of an innocent people, the legitimate owners of one of God's most beautiful islands so close to our own great, forever free and united country.

ILLINOIS ARMY.

Illinois has always been in the front when our country was

in danger. Its record during the War of the Rebellion stands foremost in the history of the nation. It gave to the nation Abraham Lincoln, who, during the dark days of the Rebellion, guided the Ship of State through many a storm and many a danger into a harbor of safety and gave freedom to a despised and degraded race. It gave to the nation Grant, who led the army from victory to victory, until the misguided but determined foe was willing to sue for peace and accept the terms offered by its conqueror. It gave the nation a Logan, whose heroic and gallant deeds brought terror to the enemy. It gave the nation an army of soldiers who took an honorable and heroic part in the deadly conflict. It gave the nation Dick Oglesby, the intimate friend of Lincoln, who happened to be in Washington on the memorable night of Lincoln's assassination. The moment the fatal shot was fired he was summoned, and when he arrived at the entrance of the house to which Lincoln had been taken, he was confronted by an armed guard who refused him admission. There was no time for argument; the sturdy Governor grasped the guard by his collar and pushed him aside like a toy, with the words, "I am the Governor of Illinois, get out of my way!"

Surgeons of the National Guard and Illinois Volunteers.

Illinois will do her share in the present conflict. When the War Department called for troops, the message was received by Governor Tanner on April 26. After a brief consultation with Adjutant-General Reece, the button was touched flashing the order over the wires to the regimental commanders in different parts of the State, and in less than thirty six hours 10,000 men were at the State Fair Grounds at Springfield ready to do their duty. General Barkley, the senior Brigadier General, was placed in command of the post, which he named Camp Tanner, and thanks to his foresight, energy and knowledge of military art, the troops received proper shelter and were assigned to their quarters immediately upon their arrival. Adjutant-General Reece demonstrated by every act that he was master of the situation. There was probably never a time when upon such short notice a temporary camp for so large a force was made more comfortable and efficient. Both of these officers, as well as their subordinates, are entitled to great credit and to the thanks of the good people of Illinois for having acted so promptly and wisely to efficiently meet such an emergency. The newspaper reporters and visitors to the camp were astonished by the fact that no complaints were made either by officers or men. Considering the limitations of equip-

ment, the number of men in the camp, the unprecedentedly disagreeable weather and the short notice, this must certainly appear as the most satisfactory proof of the intense patriotism which animated every man and made him ignore his physical requirements in the thought that he was called upon to discharge a duty to his country.

A few days after the arrival of the seven regiments of infantry and the First Regiment of Cavalry, Captain Yeager of Battery A, First Artillery, appeared in camp with a splendid body of well drilled men, which added much to the military appearance of the camp. The representatives of the United States army, Lieutenant-Colonel Roberts, Captain Swift and Lieutenants Ballou, Cole and Davis were on the field early and rendered invaluable service in the organization and mustering in of the troops. It was indeed pleasant to observe the harmony in word and action which prevailed between these officers of the regular army and the officers and men of the National Guard. This war will do much in cementing together more closely the professional and citizen soldier. In less than four weeks all of the troops were examined, mustered into the United States service and turned over to the Government.

The Fifth and Third Regiments of Infantry were the first to leave Camp Tanner amid the cheers of their comrades left

Group of Hospital Stewards Illinois Volunteers.

behind. In due time they reached their appointed station, Camp George H. Thomas, Chickamauga, Ga. The Sixth Infantry was next ordered to Camp Alger, Falls Church, Va., near Washington, and the First Infantry a few days later joined their comrades of the Third and Fifth Regiments at Chickamauga. The Second Infantry was then ordered to Tampa, but en route received notice to report at Jacksonville, Fla. The Fourth Infantry, after considerable delay, was ordered to Tampa, the Seventh Infantry to Virginia, and the First Cavalry is now on its way to Camp Thomas, Chickamauga.

GOVERNOR TANNER.

The office of governor of a State is always important and responsible, but especially so in time of war. The citizens of Illinois have reason to congratulate themselves that during the last election their choice fell upon the right man at the right time. Governor Tanner has shown that he is made of the right metal for an effective and wise war governor. His experience during the late war as a private has been of great value to him in meeting the duties of the hour. He knows what it is to serve in the ranks, and has therefore taken the deepest interest in the welfare and comfort of every soldier who has come to the camp. He is a staunch friend of the common

people (the backbone of the nation), and has catered but little, if any, to the whims and fancies of the silk stocking element. He is now more popular than ever with the National Guard. He takes pride in his army. He imbues every soldier with the idea that the highest position is within his reach if he devotes himself to his legitimate duties. He has strained every nerve in bringing his troops to the front, and has had the satisfaction of seeing an Illinois regiment the first to be mustered into the volunteer service of the United States, and that the State he represents has thus taken the lead as regards promptitude and dispatch in answering the call of the President for volunteers.

Our Governor is intensely patriotic; he has shown this in every act in the organization and equipment of the troops. It is not generally known that Governor Tanner is a great orator; the speech which he made at a banquet he gave to the officers of his staff and of the regiments in camp, was a revelation to every one present. He seemed to be inspired; his eyes flashed; every nerve and muscle responded to his intense emotion; every word and thought found a hearty response in the hearts of his profoundly interested audience. I doubt very much if he will ever be able to duplicate that speech, because such an occasion comes but once during a man's life. It was a speech which left a deep and permanent impression, a speech calculated to make a man better and more devoted to his country and his country's flag.

The Governor has visited the camp daily and always has a cheerful word and a pleasing smile for every one he meets, privates and officers alike. John R. Tanner will go down in history as a famous war governor, a worthy successor to Governors Yates and Oglesby.

MRS. TANNER.

The beautiful, youthful and accomplished wife of our Governor came to the Executive Mansion at the right time. She takes great interest in the work of her distinguished husband. She is a great favorite with the people of Springfield. She is ready in conversation and quick in perception. She visits the camp frequently and takes an active interest in the care of the sick. Her cheerful disposition and her tender care of her husband have done much to lighten the heavy burden and many perplexities, which have been resting upon the shoulders of our overtaxed Governor since he assumed the duties of his office, and more particularly since the declaration of war with Spain.

THE CAMP GROUND.

When the sudden call for troops came it was an important matter to select a camp centrally located and adapted for the season of the year. The officers of the State Agricultural Society came to the rescue of the military authorities and offered gratuitously the State Fair Grounds for the use of the troops during mobilization. The grounds occupy 160 acres of land, north of the city limits, and are easily accessible by a line of electric cars. The surface of the ground is undulating and divided by several ravines well adapted for effective surface drainage with a little expenditure of time and money. The subsoil is of clay, which in combination with the continued rains made the streets pools of mud for more than a week, a destroyer of foot gear and a rich harvest for the bootblack.

The permanent buildings were well adapted for temporary quarters for the imperfectly equipped soldier. For two weeks two of the regiments lived in tents. The camp was supplied with filtered water from the Sangamon River. A specimen of the water was sent for analysis to Dr. A. W. Palmer, professor of chemistry at the State University, who pronounced it wholesome and practically pure.

A sufficient number of sinks were dug and boarded in and the dejecta were daily covered with dry earth. Fresh straw was furnished in abundance. The rations were satisfactory both in quantity and quality.

Company B, 7th Regiment Ill. Vol., after the medical examination.

EXAMINATION OF SURGEONS FOR THE UNITED STATES VOLUNTEER SERVICE.

Soon after the troops reached Camp Tanner an order was sent from the War Department to Governor Tanner, making provision for the formation of an Examining Board. This board was to consist of one surgeon from the United States Army and two National Guard surgeons. The Government detailed Capt. H. P. Birmingham, U. S. A., stationed at Chicago, and Governor Tanner appointed Surgeon General Senn and Brigade Surgeon C. C. Carter of Rock Island, as members of the board. The duties of this board were to consist in the examination both as to physical condition and professional attainments of applicants for commissions in the Medical Department of the United States volunteers and the National Guard volunteer forces. The board was organized at once and proceeded to examine applicants for the Medical Department. The following blank was drawn up, typewritten, and presented to each applicant to fill out:

Applicants for the volunteer service are respectfully requested to fill out carefully the following blanks:

1. Name —.
2. Age —.
3. Height —.
4. Weight —.
5. Family history —.
6. Physical defects, if any, either of congenital or acquired sources —.
7. Residence and P. O. address —.
8. Command, if any —.
9. Place and date of graduation —.
10. Professional or scientific study and investigation, other than military —.
11. Foreign languages studied —; *a*, able to speak —; *b*, able to translate —.
12. Subjects or titles of books written or published, essays prepared, lectures delivered or papers read, when and where —; *a*, No. —; *b*, —; *c*, —. Remarks —.

The physical examination was made in a very thorough manner, the man being stripped, and demonstrated that the candidates for commissions in the Medical Department compared favorably with the line and field officers. Out of the whole number only three were rejected.

It was the intention of the Board, in view of the fact that most of the candidates had done good service in the National Guard for a longer or shorter period, to make the examination as broad and practical as possible. The following are some of the subjects on which the examination was conducted:

Anatomy and Surgery.—1. Give the origin and distribution of the pneumogastric nerve. 2. Mention the bones of the carpus and give their relative locations by illustration. 3. Describe the innominate artery and give its relations to surrounding structures. 4. Enumerate the different hemostatic measures and describe their technic and indications. 5. Detail the treatment of recent compound fracture of the leg. 6. Describe the different amputations through and below the ankle joint and mention the names of the surgeons who devised them.

Hygiene.—1. Give your ideas on the selection and sanitation of camps. 2. The prophylaxis and treatment of sunstroke. 3. How would you determine, in the field, in a general way, the salubrity of the water-supply, and what measures would you take for preventing its pollution?

Military surgery.—1. Give method of treating (temporary) gunshot fracture of the thigh, on the field, and when and how would you remove the patient? 2. What is the effect produced by modern small jacketed bullet, compared with the old large caliber missile? 3. Give method of procedure in rendering first aid to, and removal of, wounded from fighting line to field hospital.

Practice of medicine.—1. Describe pneumonia: Definition, etiology, morbid anatomy, symptoms, complications, prognosis, termination, diagnosis, treatment. 2. Describe cerebrospinal meningitis: Cause, pathology, symptoms, diagnosis, prognosis, treatment. 3. Describe diseases most liable to occur in tropical countries, with short description of causes, symptoms, pathology, prophylaxis, diagnosis and treatment.

Materia medica.—I. What are the more common forms of

mercury used in medicine? Write prescriptions for four. 2. Mention the comparative advantages of ether and chloroform as anesthetics. 3. Indications for the use of emetics, cathartics and alcohol.

The minimum standard was fixed at 70. It was a source of great gratification to the Board that, notwithstanding the fact that many of the applicants had been busy practitioners for years, the papers they turned in were of a high character. The result of the examination shows that in these applicants the State had desirable material for service in the volunteer regiments.

The fact that the revised code of the Illinois National Guard made provision for five surgeons to each regiment and the regulation for the United States Volunteer Service called for only three, made it necessary for the junior assistant surgeons of some of the regiments to return unwillingly to their respective homes.

As soon as the results of the examination were announced, the assignments were made. The following is a list of the medical officers of the volunteer forces of Illinois:

First Infantry. Surgeon, W. G. Willard; Assistant Surgeons, T. E. Roberts and C. B. Walls.

Second Infantry. Surgeon, G. F. Lydston; Assistant Surgeons, J. G. Byrne and G. P. Marquis.

Third Infantry. Surgeon, J. B. Shaw; Assistant Surgeons, A. F. Lenke and C. E. Starrett.

Fourth Infantry. Surgeon, T. C. McCord; Assistant Surgeons, C. M. Galbraith and G. E. Hilgard.

Fifth Infantry. Surgeon, M. R. Keeley; Assistant Surgeons, E. A. Ames and J. L. Bevans.

Sixth Infantry. Surgeon, F. Anthony; Assistant Surgeons, C. A. Robbins and L. S. Cole.

Seventh Infantry. Surgeon, T. J. Sullivan; Assistant Surgeons, G. W. Mahoney and F. P. St. Clair.

First Cavalry. Surgeon, W. Cuthbertson; Assistant Surgeons, T. J. Robeson and J. Rowe.

Battery A, First Artillery. Hospital Steward, Dr. Jackson.

PHYSICAL EXAMINATION OF FIELD AND LINE OFFICERS AND ENLISTED MEN.

The examinations were conducted at the Senate Chamber of the State House from 9 A.M. to 6 P.M. daily, with an interval of an hour for lunch. The Board of Examiners was assisted by the regimental surgeon of each regiment and his assistants. The officers were examined separately in the Lieutenant-Governor's room. One of the assistant surgeons took the chest expansion, another examined the eyes and ears and a third the head, mouth, pharynx and neck. The Surgeon-General examined the lower extremities and abdomen, and Captain Birmingham the chest and the general aptitude for active service. Colonel Carter acted as clerk in conjunction with a number of the field and line officers.

The following blanks for physical examination were drawn up, and 10,000 copies were printed and distributed to the various regiments:

PHYSICAL EXAMINATION.

Name —. Rank —. Co. —. Regiment —. Age —. Residence —. Chest Expansion —. Inspiration —. Expiration —. Are you subject to coughs or colds? —. Have you ever had any serious illness? —. Are you subject to sore throat? —. Discharge of the ear? —. Rheumatism? —. Stiffening of the joints? —. Hemorrhoids or piles? —. Fistula? —. Diarrhea or dysentery? —. Do you believe you are sound and well now? —.

Soon after the arrival of the Surgeon-General an order was issued instructing the regimental medical officers to make a preliminary physical examination of the recruits, which resulted in the return to their homes of several hundred men physically unfit for duty and which materially assisted the work of final examination. The most unenviable part of the examina-

tion fell upon the shoulders of the Surgeon-General, who for the purpose of quickening and lightening his duties devised the following commands: Heels together! Turn around! Turn back! Cough! Cough harder! which commands afterward became a favorite and familiar chorus among the men who passed the final ordeal to the satisfaction of the Board. On an average, it was found possible by following the thorough system adopted, to examine from 800 to 950 recruits a day. In all, 9899 men were examined.

The most common causes for rejection were hernia, varicose veins of the lower extremities, poor physique, heart disease, imperfect chest expansion, loss of teeth and flat foot. The presence of varicocele of different degrees in men otherwise apparently in good health was marked. It was found that nearly 25 per cent. of all those examined presented a condition of varicocele of some degree. Only two recruits were rejected for this cause, as in their cases the varicocele appeared to be

an acknowledged source of pain. In all the rest the statement was plainly made either that the applicant had no knowledge of the condition, or that it gave rise to no inconvenience. In probably one-half of all the cases the subjects were ignorant of the existence of this condition. The same remark may apply to flat foot as a cause of rejection, inasmuch as the deformity appeared to be extremely common, but only in a few isolated cases was it a cause of pain and consequently of disability for the volunteer service. The rejections for good and substantial causes were less than 10 per cent. This was influenced somewhat by the thoroughness with which the preliminary examinations had been conducted. The proportion of rejections was, on the whole, larger in the country regiments than in those made up of Chicago men. A great many men who passed the physical examination returned unwillingly to their homes by reason of the regulation reducing the number of men to a company from 109 to 84.

The intensity of the patriotic feeling which pervaded the men in camp is best shown by the illustrations which accompany this communication. The word "rejected" in many

instances seemed to make a more profound impression than would a death sentence. The disappointment would be such that the soldier was often speechless, pale, staggering, and in not a few instances hot tears would roll down the bronzed cheeks as the best evidence of the deep regret of the recruit in being deprived of the great privilege of defending the honor of his country. On the other hand, the successful soldier would accept active service with a smiling countenance and would bound away into the dressing-room like a deer pursued by hounds.

SCHOOL OF INSTRUCTION FOR MEDICAL OFFICERS.

The second day after the Surgeon-General arrived at the Camp, he sent a telegram to Professor A. D. Bevan of Rush Medical College, Chicago, requesting him to send by the earliest train a cadaver for anatomic demonstration, and a course of operative surgery. The cadaver arrived promptly and, a small amphitheater was extemporized in the Assembly Hall, which served as headquarters for the Third and Sixth Infantry. The hours between 8 and 10 P.M. were utilized in giving

LIEUTENANT-COLONEL ROBERTS.

lectures, anatomic demonstrations, and a course in operative surgery. In this course not only the medical officers, but the members of the hospital corps took an active interest. The Surgeon-General demonstrated on the cadaver emergency operations with especial reference to military surgery; one of the assistant surgeons made a dissection every day, and in the evening demonstrated his work to the class. Among the demonstrations made were the following:

Major Lydston, operations on the urethra and bladder. Major Cuthbertson, hernia operations. Major Adams, osteoplastic resection of the skull. Colonel Kreider gave a lecture at St. John's Hospital, Springfield, on Sterilization in Surgery, demonstrating his remarks by the exhibition of the means employed in the hospital for this purpose. Among the lecturers were the following: Colonel C. C. Carter, "Prescribing in Military Practice." Major Adams, "Shock and Sunstroke, and Temporary Hemostasis." Major Sullivan, "Temporary Dressing of Fractures." Major McCord, "Prevention and Treatment of Camp Diarrhea." Captain Mahoney, "Prevention and Treatment of Gonorrheal Ophthalmia." Lieutenant

Hilgard. "Treatment of Dysentery." Lieutenant Stanton, "Administration of Anesthetics." This School of Instruction was continued for nearly four weeks, and was found to be interesting, useful and well calculated to prepare the medical officers for their future work in the field. Those who took an active part in the teaching had the moral support of both field and line officers, who did everything in their power to encourage them in their work.

LECTURES ON FIRST AID.

On May 10, the Surgeon-General issued the following order: "Regimental surgeons are requested to give officers and men in their commands instruction in first aid or self help, as the case may be, in the following subjects: Diet and drink in health and disease. Care of the person, bathing, clothing, feet, etc. What to do in sunstroke. Temporary treatment of fractures. Temporary arrest of hemorrhage. Transport of injured men. Application of first aid dressings. The illustrated triangular bandage will be furnished, to be displayed in a conspicuous place in company quarters so that every man may understand its application."

These lectures were well attended and proved of signal value in preparing the line officers and men in the use of the first aid package, and in the prevention and treatment of hemorrhage, as well as enlightening them on the subjects of hygiene and sanitation.

VACCINATION.

On May 12, the Surgeon-General issued the following order:

"To all surgeons and assistant surgeons:

"Vaccination by regiments will take place as soon as they are mustered. You are directed to operate according to the following rules, assisted by your hospital stewards:

"1. The left arm is to be bared. A space four inches square at the outer border of the deltoid midway between its origin and insertion is to be thoroughly scrubbed with warm water and potash soap, then cleansed with alcohol and finally washed with pure water and dried with a pledget of absorbent cotton.

"2. The arm is to be lightly scarified where cleansed for a space of one-half inch square. Both ends of the vaccin tube are to be broken off, and the virus blown on the wound with the rubber bulb furnished, and thoroughly rubbed in with the point of the lancet. The lancet is to be cleansed with alcohol after each scarification.

"3. The arm is to be left exposed until thoroughly dry. A pledget of sterile cotton two inches square, is to be placed over the wound and held in place by an adhesive strap one-half inch wide and four inches long."

There is reason to believe that the above specific directions did much in the prevention of septic complications.

CAMP DISEASES.

The season of the year at which the troops were called out, the crowded condition of the camp, the imperfect equipment of the men, the continuous rain for over a week, and the changeable temperature were influences well calculated to test the strength and power of resistance to disease of the men who sought the service of the Government.

The appearance of cerebro-spinal meningitis on the first day the troops were in camp in the case of a man of K troop, First Cavalry, excited much interest, and as this was followed in rapid succession by three additional cases in other commands, led to a thorough investigation as to the origin and spread of this disease. This investigation was conducted by Lieutenant Colonel Kreider pursuant to an order from the Surgeon-General. Colonel Kreider presented the following report:

CAMP TANNER, SPRINGFIELD, May 23, 1898.

COLONEL N. SENN,

Surgeon-General, I. N. G., Camp Tanner, Ill.

Sir: Pursuant to your order to investigate the origin and spread of the cases of cerebro-spinal meningitis which have occurred at this camp, I have the honor to report that up to

this time three cases have appeared, all of which have resulted fatally.

1. Ernest Royal Parish, of Troop K, First Cavalry. On my request, Major William Cuthbertson assigned to the First Cavalry made the following report: "He was ailing for some days prior to enlistment. While waiting at Tattersall's at Chicago I have ascertained that he was compelled to lie down, but was up and able to pass inspection. He was taken violently ill on the train on the way down, with chills and vomiting. On reaching Springfield in the morning he was unable to walk and was removed to the Post Hospital on a stretcher. As soon as possible he was transferred from there to St. John's Hospital, where he now lies. I have just learned that another case of this disease exists at Western Springs, the patient's home." Parish died May 1. As stated in Surgeon Cuthbertson's report, he had not placed a foot on the camp ground, and his stay there did not exceed half an hour.

2. Edward B. Beebe, of the Third Infantry, residing at Elgin, was sent to the Hospital May 13 by the Surgeon of the Regiment on the eve of its departure, and was first seen by me on the following morning. In the afternoon I found him delirious, so that he required restraint and constant watching, which was given by a hospital steward of the Second Infantry. He died May 15.

3. Robert Leland, of Third Infantry, residing at Ottawa, was first seen by me at the camp at 6 P.M., May 14, and, as all ambulances were in use, was conveyed in my buggy to the Hospital. Assistant Surgeon Lemke writes of the onset of the disease as follows: "I saw him at noon, when he was complaining of intense headache. He became delirious the same night, although he was rational when aroused." The disease ran a very rapid course and death occurred May 17 at 11 P.M. From his family physician I have learned that a sister aged 20 and a brother aged 15 had died of tuberculosis. As ordered, I had intended holding a postmortem on this case, but the body was removed from the Hospital at 2 A.M. by his father.

The disease in the first case may be traced to other cases in his home town. He was not associated in any way with the men of the Third Regiment, and it seems hardly probable that the disease could have been transmitted from him to the others. It seems probable that the disease in the Third Infantry was caused by the crowded and poorly ventilated quarters which this regiment occupied, or by the damp straw on which they slept. Each of these conditions was caused by the weather prevailing during the stay of this regiment at the camp. Because of the rains the men did not leave the building during the day, and thus the rooms became foul. I called the attention of the Surgeon of the Regiment to this foul odor early in the tour; because of the rain also, the straw was brought in damp and may have figured in causing the trouble.

Respectfully,

[Signed] GEORGE N. KREIDER, Post-Surgeon.

Among the other camp diseases must be mentioned pneumonia, measles and mumps. The pneumonia contracted in the camp proved to be of an unusually malignant type. Of the thirty-two cases only two died, a mortality of about 6 per cent.

Upon the outbreak of measles an isolated part of camp ground was selected for an isolation hospital, and placed under guard with a yellow flag in front of the hospital tent. Three cases of measles and three or four cases of mumps occurred. The patients were placed in separate hospital tents, and as soon as they recovered from the illness were subjected to a thorough disinfection and their clothing disinfected before they were allowed to return to duty. This isolation of patients suffering from infectious diseases proved effectual in the prevention of a further spread of the diseases.

The ranks of the medical department were broken at an early date by the untimely death from pneumonia of Assistant-Surgeon Cole of the Sixth Infantry, who was taken ill while

en route with his regiment to Washington, and died at Fort Wayne, Ind. Upon receipt of the news of his death the medical officers drew up the following resolutions:

WHEREAS, By the untimely death of our comrade, Lieutenant L. S. Cole, Assistant Surgeon, Sixth Illinois Infantry, U. S. A., a career of brilliant promise has been cut short, be it

Resolved, That in the death of Lieutenant Cole the State of Illinois has lost a valuable medical officer and the medical profession an efficient and able member.

Resolved, That we, the members of the Medical Department, of the Illinois National Guard and United States Volunteers at Camp Tanner, extend to his bereaved family and friends our condolence and sincere sympathy.

Resolved, That copies of these resolutions be sent to his mother, and to his regiment.

(Signed.)

T. J. SULLIVAN, Major and Surgeon Seventh Infantry.

T. C. MCCORD, Major and Surgeon Fourth Infantry.

Wm. CUTBERTSON, Major and Surgeon First Cavalry.

S. C. STANTON, First Lieut. and Ass't. Surgeon, I. N. G.

Committee.

With this communication my official connection with the National Guard of Illinois is temporarily severed, as I have been mustered in as Lieutenant-Colonel and Chief Surgeon, Sixth Army Corps, U. S. V., to be assigned to the command of Major-General Wilson, Camp George H. Thomas, Chickamauga, Ga.

NEW INSTRUMENTS.

A SIMPLE ASEPTIC HYPODERMATIC AND LACHRYMAL SYRINGE.

BY SHIRLS JACKSON, M.D.

PITTSBURG, PA.

Any one who has been called upon suddenly, without adequate preparation, to use the hypodermatic syringe and found the latter out of order will appreciate a syringe that can not get out of order. The average syringe seems to spend its spare time collecting septic matter to render the injection an emulsion of dirty fat. The syringe shown in the illustration was intended primarily for ophthalmologic work, where delicacy of manipulation and thorough asepsis are imperative. In 1890 the original instrument was made for me and is still in active service.

Aside from the needle there are but two parts to the instrument; glass barrel and compression bulb. The compression bulb is that of the ordinary medicine dropper, to be had anywhere, and may be replaced in an instant. In addition to the fine needles, one of slightly larger caliber with conical point properly curved for injecting the lachrymal canal is used when the instrument is desired for this purpose. The difficulty of attaching the ordinary dropper bulb in a manner to withstand firm pressure without leaking is overcome by giving that part of the barrel a mat finish. This gives a perfect result. The caliber of this end of the barrel is so reduced and drawn out that the fluid in the barrel does not enter the bulb. The bulb of the syringe is held between the thumb and first finger, the other extremity guarded by the fourth and fifth fingers. Simple pressure, at right angles to the direction of thrust, injects the fluid without moving the needle, giving greater delicacy of manipulation than is possible with the ordinary syringe, on account of the uneven caliber of the barrel of the latter, and the firm pressure required.

Excepting the needle, there is no metal to corrode or wear out and leak; there are no sharp angles, no caps, threads, packing nor other receptacles for dirt; no regurgitating around the piston and up the operator's sleeve, and it can not dry out or

get out of order. To any one who has ever removed the piston from a syringe and tried to replace it, comment upon repairs would be superfluous. There is no piston to repair.

PUBLIC HEALTH.

Pollution of the Passaic River.—The New Jersey courts have now before them a prosecution of the City of Paterson by Jersey city to restrain the former from continuing to discharge its sewage into the Passaic River. An argument was recently made before Chancellor McGill which will, if decided in favor of the plaintiff, be the first step toward compelling Paterson and some other filth contributors to provide a modern sewage-disposal plant. The importance of this pending litigation to the public health and property values in and for the entire State of New Jersey, as well as in certain of its great cities, is great and far-reaching.—*Medical News.*

Addition to Quarantine Regulations as to Consular Bills of Health.—Referring to Treasury Department Circular dated April 26, 1894, United States Quarantine Laws and Regulations, and to Article I, paragraph 2, regulations to be observed at foreign ports, Secretary Gage issued instructions April 12, 1898, stating that the following addition is made to the consular bill of health (Form 1931 a), to be furnished vessels bound for the United States, viz.: "Number of cases of sickness and character of same while vessel was in this port, —."

Duty of Health Officer to Attend Smallpox Cases.—In the case of Reynolds vs. the City of Mt. Vernon, the second appellate division of the supreme court of New York reversed, March 22, 1898, a judgment allowing the health officer of the city \$355 extra compensation for attending three smallpox cases. One of the cases he took charge of because the physician whom he had employed under the authority of the board of health to attend it did not prove satisfactory. In another case, when he reported it, he stated to the board that he would like to make what money there was in it; and thereupon the board passed a resolution that "the health officer be authorized to employ two watchmen, a trained nurse, at \$5 a day, and attend to the case himself." As health officer of the city he was a member

of the board of health, but did not vote on the resolution; and he drew a salary of \$75 per month, which had been prior thereto fixed by the board. Judgment was given in his favor at the trial term upon the ground that the services he rendered were additional to the duties devolved upon him as health officer, and being of an extra hazardous character entitled him to extra compensation at the rate charged. But, while it says that the board of health undoubtedly had power to authorize the employment of other physicians, and create a legal charge therefore against the city, yet the appellate division does not think that the officer himself could exact extra compensation for the service which he rendered, upon the basis that such service was extra hazardous. It maintains that, although the statute under which the board acted did not specifically define the duties of a health officer, the nature of his employment and the purpose of the creation of his office sufficiently designated the character of the duties he was to perform, which it thinks necessarily embraced the character of service which was rendered in these instances. The fact, if true, that the city had prior to this time paid to another health officer extra compensation for such service, the court further maintains, did not have the effect of creating a valid claim against the city for the services in question rendered by this health officer.

A Tuberculous Residence.—The *Ohio Sanitary Bulletin* contains Dr. Gaston's story of a house at Mineral Ridge, Ohio, so manifestly the confirmed habitation of tuberculosis that the townspeople are anxious to see it destroyed by fire, so soon as it can be vacated. The writer has been informed that it was thoroughly disinfected about one year ago; that the building is very damp and the cellar in bad condition, and that in no way will other residents of the town be satisfied until it is fired. The mother of the family has refused to give up the house, although urged to do so by the remaining children. The local board of health has discussed this matter and now asks the State board to take such action as it may deem best. The house was constructed about 1830 and was occupied by a family by the name of P. It is related that a young man who lived with the family was "always ailing and in delicate health," but the only death at that time was that of a baby with bowel trouble. They resided in the premises until 1846, when the house was occupied by a family named S. They were an unusually strong and healthy family when they first came to this place, with no previous tubercular history. The first one connected with this family to pass away was a lady boarder, but information does not reveal the cause of her death. It was quickly followed, however, by the death of two sons, two daughters, father and mother, from tuberculosis, leaving only one son, who had previously gone to Illinois on account of his health, and who still survives. From 1879 till now the house has been held by the present occupants. There is no history whatever of consumption in the family prior to their coming to this house. The daughter who died recently was born here. Her death was the seventh in the family in as many years, from tuberculosis. A sister, two brothers and a mother survive, but the characteristic traces of the disease are plainly visible in faces of one brother and the surviving sister. The building is a story and a half high and surrounded by dense foliage.

Sanitary Supervision of Schools in Respect of the Control of Infectious Diseases.—Dr. Dudfield, a London health officer, has been led to discuss the above subject. There is no denying the general over-crowding of these schools which was favored by the regulations of the Education Department. The superficial and cubic space per head required for calculating the accommodation of the school was far too small; while 350 cubic feet was the lowest allowance in factories 120 was fixed by the department for schools, which to maintain a purity of .02 per 1000 of CO would demand a renewal of the air twenty-five times in an hour. But even this scanty allowance might be curtailed under certain conditions. This was dependent on the interpretation of the expression "habitual" in Clause 73 of the Code, which stipulated that the average attendance should not habitually exceed the legal accommodation by more than 15 per cent. The intention was to avoid the exclusion of a child from the appropriate class pending redistribution and the drafting of a number in excess to other classes. Memoranda and instructions had been issued interpreting the expression so as to discourage overcrowding, but it was evident that the teachers took it as permitting serious overcrowding during certain months to compensate the scanty attendance in others so long as the average for the whole year did not exceed the accommodation more than 15 per cent., a practice to which the payment to the head of the teachers of a proportion of the grants still retained in many voluntary schools was a strong inducement. It was, however, clear from Mr. Acland's explanation that the permission extended only to the temporary and unavoidable over-crowding of particular class rooms which it was the duty of the teacher to relieve as soon as possible by drafting the scholars or redistributing the classes and to occasional aggregations of the children in the principal hall or otherwise. Inadequate, however, as was the cubic space in the schools the conditions of many of the homes are no better, and the gravity of the matter lay rather in the influence of over-crowding on the spread of diseases, among which measles, not notified, widespread, highly infectious, and causing on the whole more deaths than

scarlatina and several other fevers put together, was that which had the greatest influence on the attendance, and led most often to closure and other forcible interference. The *Lancet* in considering the duty of officials as to measles and whooping cough commends the decision recently made by the Scotland Local Government Board in the direction of excluding children from school when known to be ill from those diseases, regarding it as a move in the right direction, though we fear that in times of epidemic measles and whooping cough the medical officer of health will have a somewhat busy time; doubtless, however, his emoluments will be correspondingly increased. The gradual growth of public opinion in favor of controlling those infectious diseases which hitherto have been allowed to run riot as their nature prompted them is one which will have to be encouraged gently and discreetly by the public health service. Reform lies rather in the direction of educating the public to the necessity of caution than, in the first instance at least, in resorting to injudicious prosecution. If we are to reduce the mortality from such diseases as measles and whooping cough, the exercise of tact on the part of the medical officer of health is of the utmost importance, and it is only by this means that we can gradually educate the public for the more stringent measures which may ultimately have to be taken.

BOOK NOTICES.

The Fireside University of Modern Invention, Discovery, Industry and Art. With complete indexes by JOHN MCGOVERN. Pp. 545. Chicago: M. B. Dwyer & Co., Union Publishing House, 1898.

This is a book for the masses of the people and every person may derive benefit from reading it. From the publishers' preface we extract the following: "The spirit of this book and the need for it are illustrated in the following fact: covering one, two, three, four, five city blocks, there arises the enormous glucose factory, grinding one hundred thousand bushels of corn daily. The people look with wonder upon this rising and increasing pile of buildings (whose inmates seem to be forever at toil) with no thought that at the beginning there was only a chemist at work in his little laboratory, developing certain ideas. Between his ideas, his hopes, his glass tubes and his multitudinous apparatuses and this monstrous concrete thing called the glucose factory, there is an astonishing gap in the people's knowledge. How did it come to develop so completely, before they had grasped even the idea of the chemist and the inventor? The glucose factory gives but a single illustration of what has happened on every side of us. The nickel plated ornaments, the finely spun fabrics, the beautifully colored prints, the swiftly flying street cars, the glowing splendor of the modern night lit with thousands of incandescent lamps, the astonishing cheapness of all articles that were once so costly that only a king could buy them—these things are here considered." The contents of the volume are: Electricity; X-ray; condensed air; bread, cakes and pastry; butter, cheese, etc.; fruit; nuts; spices; coffee and tea; meat; pickles, vinegar, etc.; salt; spectroscopy; chemistry; sugar; the bicycle; soap; light and heat; ice; clothes; india rubber; needles and pins; glass; paper; china; matches; astronomy. The illustrations are numerous. The scientific and historic information contained in the volume is enormous. Each chapter is complete in itself. The whole is taught by questions and answers, and the literary skill of Mr. McGovern has brought out the information in the most agreeable way. Few men past 40, however cultivated, have kept pace with the discoveries whereby our civilization has taken on its new conditions imposed by electric and chemist advances. This book will give them in brief compass a fair knowledge of the subject. For the young and for students it is invaluable.

Medical and Surgical Report of the Presbyterian Hospital in the city of New York, Volume iii, January, 1898. Edited by Andrew J. McCosh, M.D., and Walter B. James, M.D. Boards. Pp. 414. Illustrated, New York, 1898.

Besides lists of officers, staff, etc., the report contains the

following papers, many of which are accompanied by full-page illustrations of cases and temperature charts: "On Some of the Collateral Functions of a Hospital;" "An Unusual Case of Recurrent Multiple Neuritis of Uncertain Causations with Paralysis of the Phrenic Nerve—Recovery;" "Hydrochloric Acid Determinations in Gastric Contents;" "Contribution to the Surgery of the Pelvis of the Kidney;" "A Contribution to the Study of the Bacteriology of the Blood in Disease;" "Unusual Complications of Enteric Fever: 1. Suppurative Thyroiditis. 2. Purpura. 3. Eczema. 4. Neuritis of Arms. 5. Acute Cardiac Dilatation;" "A Report of Two Dermatologic Cases Complicating Cardiac Disease;" "The Malaria Fevers of New York City;" "A Report of Cases of Operation Upon the Gall-Bladder and Bile-Ducts;" "One Year's Experience with the Widal Test for Typhoid Fever;" "A Report of Three Unusual Cases of Appendicitis;" "A Case of Persistent Hiccough Yielding to Applications of Ice over the Diaphragm and to the Back of the Neck;" "A Study of a Series of Cases of Enlargement of the Thyroid Gland Examined with Special Reference to their Histology;" "A Report of Fifteen Cases of Abscess of the Brain;" "A Report of Forty-one Hysterectomies Performed During the Period of Two Years, Nov. 1, 1895, to Nov. 1, 1897, on Patients Admitted to Dr. McCosh's Service at the Presbyterian Hospital;" "Intermuscular Operations for Appendicitis with Application of the Method to Cases in which Pus was Suspected and Found;" "The Tuberculin Test for the Presence of Tuberculosis;" "The Diphtheritic Colitis of Corrosive Sublimate Poisoning;" "A Case Showing Extreme Leukemia of Lymphoid Infiltration of the Viscera;" "A Report of Two Cases of Intestinal Resection;" "A Report of Twenty-seven Cases of Pneumonia Following the Inhalation of Ether and Chloroform;" "A Contribution to the Study of Malignant Endocarditis Caused by the Micrococcus Lanceolatus;" "A Combination Stain for Ganglion Cells;" "Congenital Tumor of the Hard Palate;" "Two Cases of Amputation Through the Hip Joint;" "The Surgical Treatment of Epilepsy, with a Report of Fourteen Cases;" "A Rare Case of Septicæmia—Diffuse Suppuration of the Chest Wall;" "Some Cases of Pancreatic Hemorrhage, Pancreatitis with Fat Necrosis, and Retroperitoneal Suppuration of Unknown Origin."

Transactions of the American Pediatric Society. Edited by Floyd M. Crandall, M.D. Volume ix. Cloth. Pp. 218. Illustrated. Reprinted from the *Archives of Pediatrics*.

This volume covers the ninth session of the Society held in Washington, D. C., May 4, 5 and 6, 1897. It contains a list of presidents and officers for the years 1896, '97 and '98, members for 1897-98, meeting places, and minutes of the ninth annual meeting, besides the following papers, many of which are printed with discussion, illustrations and charts. The volume is on excellent paper, well printed and a decided credit to the Society: The President's Address, "The Evolution of Pediatric Literature in the United States;" "The American Pediatric Society's Report on the Collective Investigation of the Antitoxin Treatment of Laryngeal Diphtheria in Private Practice;" "Acetanilid Poisoning in a Newly Born Infant. Absorption From the Umbilicus;" "The Rapid Bacteriologic Diagnosis of Diphtheria;" "Bottle of Improved Form for Pasteurizing Milk and for Nursing;" "The Use of Thyroids in Disease other than Cretinism;" "Retained Intubation Tubes;" "Two Cases of Meningitis, Apparently Tuberculosis with Recovery;" "A Frequent Significance of Epistaxis in Childhood;" "Synopsis of Fifty-six Cases of Empyema Operated upon during 1896, in the service of Mount Sinai Hospital, New York, with Remarks;" "Prenatal Infection in Diseases of Infancy;" "A case of Congenital Diaphragmatic Hernia, Associated with Recurrent Attacks Simulating Asthma Dyspepticum;" "Symptomatology of Lithemia;" "Case of Varicella Gangrenosa;" "Diphtheria of the Eye;" "A Brief Analysis of One Hundred Cases of Frank Pneumonia;" "Sarcoma of the Cutis of the Newly

Born;" "Two Cases of Unilateral Tremor Occurring in Children;" "A Case of Tic Convulsif (Maladie des Tics);" "A Case of Goiter Cured by the use of Thyroid Extract;" "A Case of Exophthalmic Goiter Apparently Cured by the use of Thyroid Extract;" "Heredity and Degeneration;" "Retro Esophageal Abscess;" "Congenital Stenosis of the Larynx;" "A Report of Five Cases of Abscess of the Brain in Infants, together with a Summary of Twenty-seven Collected Cases in Infants and very Young Children."

Transactions of the Southern Surgical and Gynecological Association, Vol. x. Tenth session held at St. Louis, Mo., Nov. 9, 10 and 11, 1897. Published by the Association, 1898.

This volume contains a list of the members with their respective positions, the constitution and by-laws, the minutes of the proceedings and the papers and discussions. These have been abstracted in the *JOURNAL* and are well worthy a place in any physician's library. The editor has done his work well and the volume is handsomely printed.

Verhandlungen der Berliner medicinischen Gesellschaft aus dem Gesellschaftsjahre, 1897, Band xxviii. Paper, pp. 600. Illustrated. Berlin: L. Schumacher, 1898.

Part I contains the rules, by-laws, list of members of the society, with other data usually found in a society's transactions, and the proceedings of each session of the society from Dec. 16, 1896, to and including Dec. 8, 1897, taken up in regular order, reprinted from the *Berliner klinischen Wochenschrift*. Part 2 comprises a large number of valuable papers presented before the society. Among the contributors we notice, the names of Ewald, Harn, Baginsky, Klemperer, Bruck, Behrend, Lassar and Ewer.

SOCIETY NEWS.

A National Society to Study Epilepsy.—At a meeting held at the Academy of Medicine in New York City on May 24, representatives from eight States were present to organize a "National Society for the Study of Epilepsy and the Care and Treatment of Epileptics." Speeches favoring the formation of such a society were made by Drs. Abram Jacobi, Ira Van Gieson, C. A. Herter, Frederick Peterson, E. C. Fisher and William P. Spratling of New York; H. C. Rutter of Ohio; William M. Bullard of Massachusetts, and B. D. Evans of New Jersey; and the following officers were elected: President, Hon. William Pryor Letchworth, LL.D., New York; first vice-president, Frederick Peterson, New York; second vice-president, Prof. William Osler, Maryland; secretary, William P. Spratling, New York; treasurer, H. C. Rutter, Ohio. The society organized with forty-four members. Application for membership should be addressed to the Secretary at Craig Colony, Sonyea, N. Y.

Connecticut State Medical Society.—The tenth annual meeting of this Society was held at New Haven, Conn., May 25 and 26. The following officers were chosen for the ensuing year:

President, H. P. Stearns of Hartford; vice-president, C. S. Rodman of Waterbury; secretary, N. E. Wordin of Bridgeport; treasurer, W. W. Knight of Hartford; committee on matters of professional interest, Ralph A. McDonald of New Haven, T. T. Simpson and S. P. Overlook of Putnam; committee to nominate physicians for the Retreat for the Insane, H. S. Fuller of Hartford, E. P. Swazey of New Britain and E. K. Leonard of Rockville; publication, John Pierce and Gustavus Eliot of New Haven; honorary members and degrees, J. C. Kendall of Norfolk, H. L. Hammond of Killingly and Carl E. Munger of Waterbury; arrangements, E. P. Swazey of New Britain, C. C. Beach of Hartford, H. G. Howe of Hartford, S. B. St. John of Hartford and G. K. Welch of Hartford; annual chairman, S. B. St. John of Hartford; medical examiner, Max Mailhouse of New Haven; dissertator

C. C. Beach of Hartford; alternate, F. W. Wright of New Haven. A resolution was passed, to be sent to Congress, asking that vivisection be permitted as far as absolutely necessary. The next meeting will be at Hartford. A resolution was also passed asking that examinations for admission to practice in the State be held at stated times.

Missouri State Medical Association.—The association held its forty-first annual meeting in Kansas City, Mo., May 24, 25 and 26. Many matters pertaining to the public health were taken up and thoroughly discussed. A resolution was adopted providing for the appointment of a committee to draft a bill to be presented at the next session of the legislature creating a State board of health, and the enactment of strict sanitary laws, with provisions protecting the association from quack practitioners. Joplin was selected as the next place of meeting and the following officers chosen: S. R. Highsmith, Carrollton, Mo., president; W. A. McCandless, St. Louis, W. S. Wainwright, Kansas City, W. S. Allen, Olean, J. D. Brummell, Salisbury, W. E. Lucas, Minden, vice-presidents; A. F. Dressel, Sedalia, secretary; B. C. Hyde, Kansas City, assistant secretary; E. Van Note, Hamilton, corresponding secretary; Ed. S. Wright, Fayette, treasurer.

Iowa State Medical Society.—The forty-seventh annual meeting of this Society was held at Des Moines, Iowa, May 18, 19 and 20. Dr. H. L. Getz reported that of the \$2000 pledged toward the Benjamin Rush monument fund, \$179 had been raised, \$50 of which was contributed by the Polk County Medical Society. The Committee on Legislation made the report on osteopathy as follows:

During the past session of our legislature several bills were introduced that were against public policy and hostile to the interests of our profession, but only one of them passed.

As you all know, the senate bill, popularly known as the osteopathic bill, was carried by a majority of one in each branch of the legislature.

Your committee, together with a large number of the prominent members of this society, did not care to oppose the bill as a bill, but asked that those wishing to practice this fad in the State be required to pass an examination before the State Board of examiners on the subjects they profess to have studied, the same as any other practitioner; but a majority of our legislature in their wisdom and by the aid of a very heavy and constant lobby, saw fit to open the way for the practice of all forms of ignorance and superstitions to gain admission to our State under the cloak of this bill.

The operation of this law will do much less harm to the profession than it will to the over credulous public who is always waiting to be taken in by some new game. Yet it is very humiliating to think that our splendid medical law should be practically amended. The only consideration is that it will soon die out as do all such fads—let it alone.

Cedar Rapids was chosen as the place of meeting for 1899.

MISCELLANY.

Long intubation in infant.—A seven months-old infant, apparently dead from suffocation in croup, was revived by intubation and artificial respiration, although requiring nine insertions of the tube in twenty-two days, the tube being in the throat a total of 390 hours.—French Congress of Otolaryngology.

The Numerical Increase of Crematories.—According to the *British Medical Journal* as regards the number of crematoria, Italy comes first with twenty-four, America next with twenty-two, Germany is third with four; then come England with three, France with two, Sweden with two, Denmark with one and Switzerland with one.

The Patient and the Bicycle.—Last week a curious Nemesis restored a bicycle to its owner, a medical man, at Portsmouth. The doctor while making a call left his machine resting against the curb outside. On his coming out the bicycle had disappeared, but an hour or two later a man was brought to his

surgery suffering severely from a fall off a bicycle, which turned out to be that of the doctor.—*Medical Press and Circular*.

Radiography for Foreign Body in the Nose.—A patient complaining of purulent rhinitis was examined and a canula found in the left canal, which had been inserted and forgotten forty-two years before. The rhinitis continued and a radiograph showed that the upper end of the canula was still in the nose. It was extracted through the inferior meatus, when all disturbance ceased at once.—French Congress of Otolaryngology.

To Educate the Gullible Public.—An Irish newspaper contains a communication from Lord Maurice Fitzgerald of Johnstown Castle, County Wexford, warning the people and peasantry to avoid the "cancer curers" so numerous in Wexford. "If persons of influence throughout the kingdom would follow Lord Maurice Fitzgerald's example, and thus warn their less instructed neighbors of the perils of quackery, they would be conferring a great boon on the community."

A Missionary Hospital in Korea.—The medical missionary, J. Hunter Wells, M.D., writes from Pyeng Yang, in Korea, that a small hospital over which he presides, and accommodating between thirty and fifty in-patients, costs only \$1200. The floors in the wards are of stone, covered with clay and paper and heated underneath. The patient's board costs 12 cents per diem. The first assistant gets \$3.50 a month, the second \$3 and the errand boy \$1.80. Drugs are obtained from Japan for less than half what they cost here, and the entire expense for everything but the missionary's salary, which comes from America, was \$1000 for eighteen months. Hospital care averaged ten cents a patient.

Parturition During Paraplegia.—Routh (*Edinburgh Medical Journal*, February, 1898) relates the case of a multipara who, when about seven months pregnant, met with an accident which produced immediate and complete paraplegia. Labor began on the two hundred and sixty-first day. During the pains a feeling of "tightness" only was experienced, and when the head was passing over the perineum the cries of the patient were explained as being due not to suffering. The author offers the following conclusions that: 1. In pregnant women with paraplegia, labor may be apparently normal both as regards the period of its onset and its mode of completion, but without the sensation of pain. 2. Involution and lactation are normal. 3. Conception may take place during paraplegia.

La Grippe in Pregnancy is a serious complication and still more serious if it continues or first appears during childbirth. Bar observed an epidemic of fifty cases in his maternity service, with four deaths, last winter. Severe broncho-pneumonia appeared in five of the ten post deliverance cases. The other manifestations were varied, mostly affecting the respiratory organs, although endocarditis and purulent infection were frequent. *French Obstet. Congress*.

Operative Treatment in Fractures and Dislocations.—Nichols (*Phila. Med. Jour.*, May 28) advocates operative treatment in certain fractures and dislocations, and reports cases. In none of his cases "has the operation added anything, apparently, to the shock, but in some instances relieved it." He believes there is little danger of septic infection with a competent operator. He favors operative treatment especially in oblique fractures of the clavicle, and cites three cases, so treated, where the only deformity discernible is a small linear scar.

Concerning Rabies.—Ruhräh (*Phila. Med. Jour.*, May 28) reports on "A Year's Work in the Preventive Treatment of Rabies," the results of an investigation through the Pasteur Department of the College of Physicians and Surgeons, Baltimore, Md. Thirty-five cases were treated and he shows, contrary to the general opinion, that there is "very great prevalence of the disease in this and adjoining States." Seventeen of

forty-two dogs examined proved to be rabid. None of the thirty-five cases treated have so far shown any signs of the disease. Of these, twenty-five were bitten by animals which were, in the laboratory, proved to be rabid. In the other ten cases rabies was suspected, but the dogs could not be obtained for experimental purposes.

Dosage of Antitoxin.—An increased amount of antitoxin is required to neutralize a toxin, if the coagulating property of the blood is reduced. Experiments at Marburg have demonstrated the fact that if the blood of guinea pigs, rabbits, pigeons, hens, be deprived of its coagulability with sodium citrate, twenty-five to fifty times as much antitoxin is required to neutralize the fatal dose of tetanus toxin, and one hundred times for diphtheria toxin. This fact is not identical with Ehrlich's discovery that a toxin molecule may retain its antitoxin binding property, while losing its toxicity, in which case it becomes a toxoid, as he has observed after weakening the strength of tetanus toxin with iodine trichloride. The question now is, what element in the blood thus checks the toxin-neutralizing power of the antitoxin, and also whether the toxin or the antitoxin is affected, or both, and the import of the discovery from a therapeutic point of view.—*Deutsche Med. Woch.*, May 12.

Immunization.—The Ehrlich theory of immunity which has led to important results in the past three months is thus concisely stated by Behring: 1. A toxin only produces its specific disease in those individuals who already possess a substance in the living cells or tissues which has a chemical affinity for the toxin. 2. When this substance passes out of the tissues into the blood, it becomes a protecting and curing substance. In other words, the same substance which stored in the cells, is the preliminary and indispensable condition to an intoxication, transferred into the circulation, cures it, recalling Hippocrates' "what causes the disease, cures it," but unlike this, susceptible of scientific demonstration, as many have already reported, *vide JOURNAL*, pages 1290, 1127, 449. Wernicke has saved guinea pigs inoculated with a fatal dose of anthrax, by administering spleen substance, after killing the anthrax bacilli in it, thus causing the production of sufficient anti-bodies to subdue the infection. Pfeiffer has also recently announced that the cholera protecting bodies are accumulated in the blood-producing organs much more abundantly than in the blood itself. The application of this theory in therapeutics is more or less dangerous, as a certain degree of intoxication must be attained in order to start the production and dissemination of the anti-bodies, especially in cases in which there is already an advanced condition of irritability, evidenced by fever. Koch now refuses tuberculin treatment altogether to patients with fever. But these patients are the very ones who will benefit most when we finally succeed in supplying directly to the blood such a powerful toxin-binding substance that the effect will be accomplished without compelling the organism to extra work.—*Deutsche Med. Woch.*

Relief Associations.—The patriotic women of the United States being debarred the privilege of fighting for their country, are organizing for relief purposes in many cities and States. The last circular that we have seen relating to relief committees, was issued by the ladies of Providence, R. I. It sets forth that the reader is cordially invited to become a charter member or member of the Rhode Island Sanitary and Relief Association which is being formed for the purposes of sending comforts to our sick and wounded soldiers and sailors (under the directions of the surgeon generals of our army and navy), and also as far as possible to assist deserving families of enlisted men, residents of Rhode Island. The headquarters of the Association is in Room 221, Banigan Building, Providence, but branches will be formed in every city and town in the State. Charter members (women only) pay \$10 initiation fee and \$1

annual dues. Members (men and women) pay \$1 initiation and \$1 annual dues. "It is not too early to organize relief committees, for already one great battle has been fought, and we know not how soon the horrors of war may be at our very doors. Will not every patriotic man and woman in our State come forward and share in this work?" On the advisory board are His Excellency Governor Elisha Dyer and two original members of the Sanitary Commission of 1861, Rt. Rev. Thomas M. Clark and Professor Walcott Gibbs. Among the names of the promoters of the movement are those of Mrs. A. Livingston Mason, president of the Society of Colonial Dames in the State of Rhode Island; Miss Sarah E. Doyle, president of the Society for the Collegiate Education of Women; Mrs. Anna Garlin Spencer, president of Local Council of the Women of Rhode Island, affiliated with the National Council; Mrs. Henry L. Ballou, State Regent, Daughters of the American Revolution; Miss Ellen G. Hunt, president Rhode Island Women's Club, and many others.

A Visit to Dr. Schenk of Vienna—the "Sex Regulator."—Dr. Neesen of Brooklyn, who has been taking a post-graduate course at Vienna, writes of a visit to Professor S. L. Schenk: "When I called at Dr. Schenk's house I found the street blocked with carriages of all descriptions. A group of well-dressed people stood on the stoop of the house, waiting to be admitted. The anterooms were crowded to suffocation with visitors, most of them women, richly attired and genteel looking, all waiting to consult the professor.

"Dr. Schenk told me: 'I have been making experiments for the last twenty years, but the profession must decide whether or not I have discovered anything new. The wife of a Parisian journalist was sent to me by her physician. She was despondent because of her lonely home. I assured her that I could help her, and then with my experiments in mind, I asked her if she desired a boy or girl. She replied that both she and her husband wanted a boy. The woman underwent treatment, and in due course of time she had born to her a bouncing boy of twelve pounds weight. The husband was so overjoyed that he told the experience to his friends, and so it got into the newspapers. I am persuaded that the quality and quantity of the food digested has largely to do with the production of male or female offspring. Drugs are used to some extent, but they have no specific action on the determination of the sex. I use them simply as a means of raising or lowering the state of the general health.

"I began twenty years ago treating animals, and I met with such success that I began experiments with human beings. Many persons have been misled by the incorrect reports that have got abroad about this treatment. The rooms out there are full of such. They come here wholly misinformed and expect me to do the impossible. They are pestering me constantly. I have, so far, endeavored to see every one and treat them courteously, but the task is getting too arduous."

"Dr. Schenk has been unable to attend to his regular practice since his discovery began to be talked about. All of his household arrangements have been interfered with. He has had to slip out at the side entrance to avoid the crowd in front of his house. He has given out, again and again, the statement that he will not accept any fee for practicing his system, nor treat any patients except those whom he selects for experimental purposes and whom he places in his sanitarium."

His pamphlet propounding his theories has just appeared, and is the sensation of the day abroad. He believes that the most vigorous parent determines the development of the ovum, whether it is to remain a female, an inferior being, or develop further into a male. This influence of the parent on the sex is always a *crossed* influence; the male parent engenders a female, and the female, a male. All that is necessary, therefore, is to build up the would-be mother to such a condition of health and vigor that her influence preponderates, and behold,

a son! If examination of the urine shows more or less glycosuria, then the woman is not in perfectly normal conditions and her diet must be regulated until all traces of sugar disappear, commencing several months before conception and continuing for three to four months afterward. Already the drug stores are placarded: "Analysis for sugar while you wait," and the medical press is observing that fortunately for the theory there are only two sexes.

The Hospital Corps of the Volunteer Army.—An obstacle in the way of obtaining men for hospital and ambulance duty with the Volunteer Army has been removed. The act authorizing the levy of troops made no provision for members of a hospital corps. Privates of the Hospital Corps of National Guard regiments could not be mustered as such into the service of the United States. They were accepted as privates of the line with the expectation that when a hospital corps was formed they would be transferred to it. No volunteer hospital corps has been formed, but authority has been granted for the transfer of men from the line of the volunteer organizations to the Hospital Corps of the Regular Army. Moreover, the regulations governing the assignments of active hospital stewards and the appointment of hospital stewards of the Regular Army were found to be inapplicable to the conditions existing in a hastily formed military force. Under these regulations a year's service as a private in the corps was a preliminary requirement to promotion to the position of acting hospital steward. The following orders, No. 58, Headquarters of the Army, Adjutant General's Office, May 31, 1898, modify these regulations and permit of the organization of a hospital corps suitable to the needs of the seven Army Corps now being formed:

Enlisted men of the volunteer organizations may be transferred to the Hospital Corps of the Regular Army by the Commanding General of the Army Corps in which the soldier is serving, upon the recommendation of the Chief Surgeon of the Corps.

The provisions of Army Regulations governing the Hospital Corps so far as they are inapplicable in the time of war and with troops in the field are hereby suspended during the existence of such conditions.

The Commander of an Army Corps, or of a Division or Brigade acting independently of a Corps, is charged with the full control of the transfer from the line, the enlistment, re-enlistment and discharge of members of the Hospital Corps of his command, with the detail of acting hospital stewards and the appointment of hospital stewards.

Acting hospital stewards will be detailed from privates of the Hospital Corps who are recommended by their medical officers as possessing the necessary qualifications. Hospital stewards will be appointed from acting hospital stewards who are recommended by their medical officers and who have served not less than three months in the Hospital Corps and are approved by a board of not less than three medical officers.

Enlistment papers in duplicate, examination forms and outline figure cards for members of the Hospital Corps will be forwarded to the Surgeon General's Office, as now required, and monthly reports will be made by the chief surgeon of the Corps, or Division if acting independently, showing the number of stewards, acting stewards and privates on duty, the names of men transferred from the line, of those enlisted or re-enlisted, discharged, died, detailed acting hospital steward, or appointed hospital steward.

The quota of members of the Hospital Corps for a corps of 25,000 men, is:

	Hospital stewards.	Acting hos- pital stew- ards.	Privates.
For each regiment of infantry	1	3	1
For each artillery battalion, 3 light batteries	1	3	1
For each regiment of cavalry	1	3	1
For each corps headquarters	1	3	1
For each division headquarters	1	3	1
For each brigade headquarters	1	3	1
For each division ambulance company and for the reserve corps company	7	3	104
For each division field hospital and for the reserve corps field hospital	6	3	90

The three volunteer hospital stewards mustered in with each regiment are included in this strength.

The Corps Commander may make such distribution of the members of the Hospital Corps within his command as he considers for the best interests of the service.

Pure Water for the Troops.—The following is the text of Surgeon-General Sternberg's Circular, dated May 31, referred to in our editorial on another page:

The Quartermaster General has been authorized to provide filters for the use of the Army. The filters recommended by the Surgeon General are the Berkefeld cylinder and the Maignen asbestos filter. These filters are intended to supplement each other, and the use of both is required to obtain a plentiful supply of water free from the germs of disease. Medical and company officers should have a thorough understanding of the intention and action of each of these filters that the full benefit of their use may be ensured to the troops. The Berkefeld filter is a specially prepared earthenware cylinder through the pores of which the water has to be forced by the exercise of considerable piston pressure. The pores are so small that they exclude or filter out, not only all particles which would give a turbidity or cloudiness to the water, but those more minute particles which are the active agents in the production of typhoid fever and other camp diseases. The filter is, therefore, an efficient filter, but the smallness of the pores which gives it its efficiency constitutes an objection to its use in practice. Its pores speedily become choked by a coating of filtered particles. If greater pressure be used to increase the rapidity of filtration, the connections of the cylinder may become strained and the filter be rendered valueless, while if the cylinder be removed and its surface scrubbed it is exposed to the risk of fracture unless handled with the utmost care. The Maignen asbestos filter has larger pores than the other. Water passes through it more readily and under slight pressure. The coarser particles which give a cloudiness or turbidity to a water are strained out; but as the germs of disease are not excluded the filtration from the sanitary point of view is not efficient. It will be seen, however, that the Maignen filter may be put advantageously to use in preparing water for purification by the Berkefeld cylinder. By straining out the particles which otherwise would choke the Berkefeld filter, it enables the latter to operate as rapidly as itself and does away with the necessity for increased pressure or frequent interruptions for scrubbing the porous cylinder. To use the two filters in combination, the bucket or other receptacle containing the unfiltered water and the asbestos filter should be fixed securely at a height of five or six feet from the ground. From this bucket the clear, but not necessarily pure, water is delivered by the rubber tube of the filter into another bucket properly placed to receive it and to admit of the pumping of the filtered water through the Berkefeld cylinder into vessels for storage or use. It has been found that asbestos filtered water can be rendered sterile by the Berkefeld apparatus at the rate of about five gallons in twelve minutes, the pump working easily. The outer covering of the Maignen filter should be kept free from deposits of clay or other matters by brushing or scrubbing. If need be the outer casing of asbestos cloth may be removed, washed and replaced. The filter, as a whole, may be sterilized, when necessary, by boiling in water. When not in use it should be exposed to the air as much as possible. The Berkefeld filter is worked by placing the pump in the vessel containing the asbestos filtered water, with its nozzle resting firmly on the bottom. The piston is then worked without jerking while counter pressure is made with the left hand on the top of the barrel. To keep the cylinder in perfect condition, when thus used, it should be sterilized every fourth day. The thumb screws on top should be unloosed and the cylinder having been lifted carefully from its metal case, should be put in water of ordinary temperature which should be brought to the boiling point and kept at this temperature for five minutes. When removed from the hot water it should be allowed to cool before being replaced for use. The cylinder is liable to become cracked and useless by sudden changes of temperature. If a cracked or worn out cylinder has to be replaced the small wheel should be unscrewed from the lower end of the old cylinder and screwed upon the new one. The nut at the bottom of a cylinder should never be unscrewed.

Appointments and Assignments of Army Medical Officers.—Chief Surgeons of Divisions were recently assigned by the Secretary of War as follows:

Majors Clayton Parkhill, James H. Hysell and Jefferson D. Griffith, Surgeons, U. S. Volunteers to the divisions of the 1st Army Corps, Major General John R. Brooke, U. S. Army, Commanding, at Chickamauga National Park, Ga. Majors

George Cook, Leonard B. Almy and Charles B. Nancrede, Surgeons, U. S. Volunteers to the divisions of the 2d Army Corps, Major General William M. Graham, U. S. Volunteers, Commanding, at Falls Church, Virginia. Majors Louis Schooler, James M. Jenne and Henry F. Hoyt, Surgeons, U. S. Volunteers to the divisions of the 3d Army Corps, Major General James F. Wade, U. S. Volunteers, Commanding, at Chickamauga National Park, Ga. Majors John M. G. Woodbury, R. Emmitt Griffin and Thomas C. Kimball, Surgeons, U. S. Volunteers to the divisions of the 6th Army Corps, Major General James H. Wilson, U. S. Volunteers, Commanding, at Camp George H. Thomas, Chickamauga National Park, Ga. Majors Thomas E. Evans and Eduard Boeckmann, Surgeons, U. S. Volunteers, to divisions of the 7th Army Corps, Major General Fitzhugh Lee, U. S. Volunteers, Commanding, at Tampa, Florida. Other assignments have been made as follows: To the expeditionary force for the Philippine Islands, Captains Frank R. Keefer and Paul F. Straub, U. S. Army; Acting Assistant Surgeon George H. Penrose to the Utah Batteries forming part of the command; Major Herbert W. Cardwell to duty as Chief Surgeon of a division in the Department of the Pacific; arrangements have been made for the relief of Captain Guy L. Edie, U. S. Army from St. Michaels, Alaska. To the General Hospital at Key West, Florida, Acting Assistant Surgeon A. H. Mann, U. S. Army. To the General Hospital at Fort McPherson, Georgia, Acting Assistant Surgeon James H. McCall, U. S. Army. To Fort Monroe, Virginia, Acting Assistant Surgeon W. P. Chamberlain. To Tampa, Acting Assistant Surgeons R. M. Geddings and Thomas R. Marshall, U. S. Army. To the Hospital Ship *Relief*, Acting Assistant Surgeon Wm. M. Gray, U. S. Army, from duty at the Army Medical Museum, Washington, D. C. Many appointments as Chief Surgeons of Brigades, and divisions with the rank of Major in the Volunteer Army have been sent to the Senate for confirmation. The senior captains and assistant surgeons of the Regular Medical Department have the lead in these appointments. The following is the list of nominees:

To be Chief Surgeons of Division, with rank of major—Capt. Wm. H. Arthur, assistant surgeon U. S. army; Capt. George E. Bushnell, assistant surgeon U. S. army; Donald MacLean of Michigan; George R. Fowler of New York.

Captains and assistant surgeons U. S. army, to be Brigade Surgeons, with rank of major—Wm. C. Gorgas, Henry P. Birmingham, Marlborough C. Wyeth, Richard W. Johnson, Edward C. Carter, Wm. O. Owen, Peter R. Egan, Wm. J. Wake-man, Wm. Stephenson, Adrian S. Polhemus, John L. Phillips, Wm. C. Borden, Edgar A. Mearns, Guy L. Edie, Wm. D. Crosby, Wm. L. Kneeder, Charles M. Gandy, James E. Pilcher, Charles B. Ewing, Walter D. McCaw, Jefferson R. Kean, Henry I. Raymond, Francis J. Ives, Wm. P. Kendall, Edward R. Morris, Henry S. T. Harris, Wm. B. Banister, Paul Clendenin, Charles E. Woodruff, Capt. Eugene L. Swift, Paul Shillock, Ogden Rafferty, Chas. F. Mason, James D. Glennan, Alfred E. Bradley, Philip G. Wales.

To be Brigade Surgeons, with rank of major—Willis MacDonald, Charles M. Drake of Georgia, Joseph K. Weaver, John Guiteras of Pennsylvania, Charles E. Ruth of Iowa, John W. Bayne of the District of Columbia, Milo B. Ward of Missouri, Schuyler C. Graves of Michigan, George T. Vaughan of marine-hospital service, Nathan S. Jarvis of New York, Wm. Devine of Massachusetts, John C. Martin of Ohio, Peter D. Machaughaton of Michigan, Samuel T. Armstrong, acting assistant surgeon; John Patterson Dodge of Ohio, John R. McDill of Wisconsin, Samuel O. L. Potter of California, Geo. A. Smith of Iowa, Arthur Snowden of Virginia, R. Stansbury Sutton of Pennsylvania, Frank Bruso of New York.

Philadelphia.

HOMEOPATHS FOR THE ARMY AND NAVY OF THE UNITED STATES.—The homeopaths of Philadelphia have applied direct to President McKinley for recognition in the army and navy of the United States of America and the executive has promised them that no discrimination in this matter will be allowed. This may be a test then as to what homeopathy really means. If they give the same medicines and operate according to the teachers of surgery throughout the world then what is the difference between homeopathy and medicine? At any rate, the homeopaths of Philadelphia told Governor Hastings that they had been discriminated against. They stated that the Governor had explained that all the medical officers were appointed first by the colonels of regiments and that such applicants were subsequently confirmed by the adjutant generals. He further stated that if any case came before him in which any discrimination was shown he would call for an investigation. A case

has been cited in which a homeopath by the name of Dr. William F. Satchell desired to enlist in the Pennsylvania Naval Reserves and was told that it was purely an "old school" organization. At the recruiting office they told him that those who practiced homeopathy might enter the hospital corps as privates but could not enlist as surgeons or assistant surgeons. The gentleman of that denomination also states that one of their number applied to Surgeon-General von Ripen who told him (Dr. Thomas H. Hollinshead) "that there was no chance whatever for him, but in truth he was in favor of having a few homeopaths in the service as it would be a great saving to the Government by doing away with a large drug bill since graduates of that school cured almost entirely by faith." These homeopaths took a final appeal and sent a delegation direct to the President. They were introduced by a senator from Pennsylvania (Penrose) and General Bingham. President McKinley, it is stated, received them cordially. After they had stated their case he told them that he had reviewed the subject and could find no law to prevent them from becoming surgeons and assistant surgeons in the army and navy provided they passed the examinations. It is supposed that this Committee left happy and it is said they will notify aspirants to make applications and pass the examinations.

PHILADELPHIA FOR CLEAR WATER.—The people of this city are still drinking water so contaminated with mud and coal dust that it is becoming almost unbearable. A great many remedies have been suggested, but the fact remains that the water is not clear. Recently a committee was appointed to make an investigation along the banks of the Schuylkill and try to find out the origin of the evil. The health officer Dr. Benjamin Lee now thinks the city will have to give up the Schuylkill water entirely and tap the Delaware River a number of miles above the large cities. This question is by no means settled, and out of the thousand and one remedies offered by councilmen and all, not one has been accepted to bring about the proper solution of a subject of most moment to any city or village of this country.

STATUE FOR DR. NATHANIEL CHAPMAN.—By the will of Dr. Samuel Jackson, formerly Emeritus Professor of the Institute of Medicine of the University of Pennsylvania (1835-1863), the sum of \$3,000 has been left for the erection of a statue to the memory of Dr. Nathaniel Chapman, Professor of Materia Medica at the University of Pennsylvania (1813-1816) and afterward Professor of Practice of Medicine (1816-1850). It was the expressed desire of the benefactor to have the monument erected on Ninth Street "between the two college buildings," but as that space is now occupied by the post-office this request can not be carried out and a new site will consequently be chosen.

DR. GUY HINSDALE HONORED.—The Boylston prize offered by Harvard University has been awarded to Dr. Guy Hinsdale for his monograph on "Acromegaly."

GOOD-BYE TO BAD WATER.—The sanitary commission recently appointed by the Board of Health of Philadelphia recently made a tour of inspection of the Schuylkill river to find out the source of pollution. They found it in several places without much trouble. Sewage, coal dust and other varieties of filth pour into this stream constantly. After a great deal of hard work by the organized medical societies and health commission, \$3,700,000 will be spent in establishing a proper filtration plant provided the select council will concur. Drs. William Pepper and John K. Mitchell have been two of the most unceasing workers among physicians for better water.

NEW PROFESSOR OF OBSTETRICS. At a recent meeting of the officers of the Medico Chirurgical College, Dr. George M. Boyd was elected clinical professor of obstetrics. Dr. Boyd is a graduate of the University of Pennsylvania and an ex-resident of the Episcopal Hospital, this city. He is a member of the County and State Medical Societies, the College of Physicians and of the American Medical Association.

HEALTH PROTECTIVE ASSOCIATION. Dr. E. D. M. Sajous of Philadelphia will endeavor to organize a commission, composed of physicians, to devise health rules to be observed in the tropic countries during the war.

SUPPOSED PTOMAIN POISONING.—Three men of Philadelphia recently prepared a dinner, the principal article of which was pork. A short time after the meal all three became quite ill with symptoms of trichinosis, but subsequent examination proved absence of trichinae and it is now supposed the meat when bought was in a state of decomposition, giving rise to the symptoms produced.

MORTALITY STATISTICS.—At noon, May 28, there had been for the week past a total of 409 deaths, an increase of 26 over the preceding week. Of these, diphtheria caused 10 deaths,

typhoid fever 8, scarlet fever 4, as against 20, 7 and 3 deaths for the week preceding. Of the total number of deaths, 121 were children under five years of age.

Impassible Constriction of Esophagus. Rosenheim recently performed gastrostomy on a child for this cause, and all food was taken through the gastric fistula, until the restriction was reduced by laminaria and an inflated rubber ball. Ewald has frequently observed these constrictions subside spontaneously after gastrostomy.

ASSOCIATION NEWS.

The Denver Meeting.

LINCOLN, NEB., June 5, 1898.

The special train of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION left Chicago at the tick of the clock 11 P.M. Saturday. All the reservations were taken with the exception of those reserved for members in Iowa and Nebraska, who intended to join en route. The equipment of the train was superb, with every convenience and accommodation for the passengers. The party up to this point are very happy and seem to be enjoying themselves immensely. The train consists of nine Pullman sleeping cars, two dining cars and a baggage car. It required two engines to haul the train from Burlington. The following comprised the party as it arrived at Burlington:

A. P. Clarke & daughter, Cambridge, Mass.
Wm. E. Upjohn & wife, Kalamazoo, Mich.
E. F. Ingals, Chicago.
A. Hakanson & wife, Chicago.
Frank C. Greene, Chicago.
H. N. Greene & wife, Chicago.
Miss Moore, Chicago.
Chas. Truax, Chicago.
M. L. Harris, Chicago.
F. C. Hotz & wife, Chicago.
N. J. Smedley, Chicago.
Geo. C. Prussing, Chicago.
Jos. Eastman & daughter, Indianapolis.
J. A. Horn & wife, Manch Chunk, Pa.
N. E. Woessner, Huron, Ohio.
L. C. Taylor, Springfield, Ill.
W. D. Storer, Chicago.
Frank Burridge, Chicago.
Frank T. Stevens, Mt. Pleasant, Ia.
J. M. Postle & wife, Hinckley, Ill.
L. E. Munson, Mt. Pulaski, Ill.
Miss Katie Mason, Brighton, Ia.
M. C. Terry & wife, Brighton, Ia.
C. B. Stockwell, Port Huron, Mich.
E. E. Tansey & wife, Chicago.
A. C. Taylor, Baldwinville, N.Y.
J. S. Marshall, wife & son, Chicago.
E. H. Root, Chicago.
T. S. Conley, Chicago.
M. S. Hosmer, Ashland, Wis.
Jas. P. Stimpson, Pittston, Pa.
H. S. Mead, Lima, Ohio.
D. W. Sterne, Lima, Ohio.
Frank M. Mason, Rossville, Ill.
Mrs. Kate M. Mason, Rossville, Ill.
Daniel R. Brower, Chicago.
H. S. Mead, Kalamazoo, Mich.
J. H. Stealey & wife, Freeport, Ill.
J. W. Long & wife, Bryon, Ohio.
Louis L. Gregory, Chicago.
Allen Salter, Lena, Ill.
A. C. Gatchell, Worcester, Mass.
Alex. McAllister, Camden, N. J.
G. W. Johnson, Chicago.
A. B. Campbell & wife, Syracuse, N.Y.
A. H. Tagert & daughter, Chicago.
A. E. Miller, Boston, Mass.
C. W. Bassett & wife, Chicago.
H. A. Bremmer & wife, Merritt, Ill.
G. H. Eiskamp, Washington, Iowa.
H. A. Spangler & wife, Carlisle, Pa.
J. H. Jackson, Bucyrus, Ohio.
F. E. Bell & daughter, Chicago.
Hugh McCall, Lapear, Mich.
Hon. Alonzo Garcelon, Lewiston, Me.
Miss Garcelon & friend, Lewiston, Me.
P. W. Werner & wife, Joliet, Ill.
Owen O'Neal, Chicago.
B. D. La Force, Ottumwa, Iowa.
Warren B. Hill, Milwaukee, Wis.
H. M. Brown, Milwaukee, Wis.
Letitia A. Westgate, Sycamore, Ill.
W. H. Earles, Chicago.
G. V. I. Brown, Milwaukee, Wis.
J. M. Anders, Philadelphia, Pa.
L. Tibbets & wife, Rockford, Ill.
J. T. Priestley, Des Moines, Iowa.
C. M. Hobby, Iowa City, Iowa.
Ernest Laplace, Philadelphia.
Marie J. Mergler, Chicago.
F. J. Whitney, Leominster, Mass.
James H. Hagenbuch, Mahanoy City, Pa.
Chas. Davidson, Chicago.
J. V. Shoemaker, Philadelphia, Pa.
C. T. Hoffman, Morea Colliery, Pa.

[SPECIAL STAFF CORRESPONDENCE.]

DENVER, June 8, 1898.

The Denver meeting will pass into medical history as one of the most pleasant, enjoyable and profitable meetings the ASSOCIATION has yet held. The arrangements were well carried out, and the various Sections carried out their programs on schedule time and were well attended. The registration reached twelve hundred on Tuesday, a remarkably large number when it is remembered that many of our members are now in the service of the United States Government.

The meeting was called to order by Dr. J. L. THOMPSON, Second Vice-president, in the absence of President STERNBERG, whose official duties compelled him to remain in Washington. After prayer by the Rev. W. F. McDOWELL, the ASSOCIATION was welcomed by His Excellency, ALVA ADAMS, Governor of the State; by the Hon. W. S. McMURRAY, mayor of the city, and by Dr. J. W. GRAHAM of Denver. The Governor's address was eloquent, witty and patriotic. The others were of high order and were received with great enthusiasm. After the reading of the President's Address a telegram of congratulation was sent to Surgeon-General STERNBERG.

The Nominating Committee selected the following officers for the ensuing year: President, JOSEPH M. MATHEWS of Louisville; First Vice-president, W. W. KEEN, Philadelphia; Second Vice-president, J. W. GRAHAM, Denver. Annual orations to be delivered by J. C. WILSON, Philadelphia, on Medicine; ALEXANDER McRAE on Surgery, and D. R. BROWER on State Medicine. The city of Columbus was selected as the next place of meeting.

The Section Dinners held Tuesday evening were well attended. The Sections on Surgery and Gynecology held a joint dinner, where patriotism and the red, white and blue ruled the exercises. The toasts were: "Our Absent Members," W. W. KEEN, Philadelphia; "The United States Army, 1861 to 1865," P. S. CONNER, Cincinnati; "The Confederate Surgeon," JOSEPH PRICE, Philadelphia; "Our Modern Navy," SHERWOOD DURK; "The Medical Corps, United States Army," CURTIS E. MUNN; "Our New Sanitary Problems," Jos. M. MATHEWS, Louisville. W. L. RODMAN of Louisville presided admirably, and the local committee of arrangements sang patriotic songs between the speeches. Deep feelings of patriotism and of sympathy with our army and navy pervaded the entire assembly, and the occasion was one long to be remembered by those in attendance and was calculated to bring out the best efforts of the speakers.

At the meeting of the American Academy of Medicine held Monday the following officers were elected for the ensuing

year: President, Dr. Edward Jackson, Denver; first vice-president, Dr. W. L. Estes, South Bethlehem, Pa.; second vice-president, Dr. J. T. Searcey, Tuscaloosa, Ala.; third vice-president, Dr. William Elmer, Trenton, N. J.; fourth vice-president, Dr. Robert H. Babcock, Chicago; secretary and treasurer, Dr. Charles McIntyre, Easton, Pa.; assistant secretary, Dr. W. L. Pyle, Philadelphia.

The American Medical Editors held an instructive meeting and Dr. T. H. Hawkins of Denver was elected president. The banquet was well attended. Dr. I. N. Love of St. Louis presided as toastmaster and speeches were made by various members of the editorial fraternity.

The Association of American Medical Colleges had a full attendance, several new colleges being admitted to membership. A committee was appointed to draft a new constitution. The following officers were elected for the ensuing year: President, H. O. Walker, Detroit; senior vice-president, Dr. H. Bert Ellis, Los Angeles; junior vice-president, Dr. G. E. Woody, Louisville, Ky.; secretary and treasurer, Bayard Holmes, Chicago.

CHANGE OF ADDRESS.

Aldridge, H. W., from Galveston, to Hitchcock, Texas.
Abbott, J. B., from Richmond to West Appomattox, Va.
Baumgarth, N. R., from Milwaukee, Wis., to 425 South Clark Street, Chicago, Ill.
Bell, I. A., from 389 Elm Street to 137 N. Akard, Dallas, Texas.
Burkhart, J. R., from Ft. Madison, Ia., to 526 20th Street, Rock Island, Ill.
Condon, A. S., from Ogden City, Utah, to Fort Bayard, New Mexico.
Collins, T. S., from Keokuk to Ryan, Iowa.
Clements, G. E., from Chicago, Ill., to Crawfordville, Ind.
Campbell, J. G., from St. Luke's Hospital, to 507 Lexington Avenue, Chicago.
Chapman, R. M., from 417 Walnut Street, to 510 Walnut Street, Des Moines, Iowa.
Cahill, L. L., from Chicago, Ill., to Elizabethtown, New Mexico.
Cohoe, W. H., from Burnsville, to Elizabethtown, Ind.
Cavenaugh, J. J., from Omaha, Neb., to St. Paul, Kan.
Canfield, B. V., from 325 Virginia Avenue to 525 Virginia Avenue, Indianapolis, Ind.
Dunlap, F., from Bloomington, Ill., to Danville, Ind.
Evans, W. A., from 116 13d Street, to 103 State Street, Chicago, Ill.
Fehr, H., from Milwaukee, Wis., to Augustana Hospital, Chicago, Ill.
Greensfelder, from 3500 Ellis Avenue, to 2512 Michigan Avenue, Chicago, Ill.
Haynes, H. A., from Estherville, Iowa, to Harvey, Ill.
Hudkins, B. I., from Richmond, to Overfield, Va.
Hoff, F., from 58 Walnut to 510 Walnut Street, Des Moines, Iowa.
Heugst, D. A., from 1005 Park Bld'g., to Home Bld'g., Pittsburg, Pa.
Hull, A. R., from Chicago, Ill., to Sanitorium Waldheim, Oconomowoc, Wis.
Holman, J. H., from Columbia to Hartford, Mo.
Jacobson, F. F., from 150 Orange Street to 306 Perry Street, Cleveland, Ohio.
Jones, R. L., from Nashville, Tenn., to 433½ Anstin Avenue, Waco, Texas.
Langher, C., from 7137 Langley Avenue to 7107 Langley Avenue, Chicago, Ill.
Little, J. A., from Chicago, Ill., to Logansport, Ind.
Meany, J. E., from Reedsville to Manitowoc, Wis.
Maxwell, C. S., from Richmond, Va., to Mount Olive, N. C.
McCurdy, S. L., from 1623 Park Bld'g., to Home Bld'g., Pittsburg, Pa.
Moellir, T. O. E., from Thief River Falls, Minn., to Hillsboro, N. D.
Ornet, A. L., from Des Moines, Iowa, to Hiteman, Iowa.
Patterson, M. F., from 506 Walnut Street to 600 Walnut Street, Des Moines, Iowa.
Potter, L. C., from 351 W. 28th Street to 142 E. 83d Street, New York.
Spencer, J. G., from 370 Central Avenue to 341½ Prospect Street, Cleveland, Ohio.
Tollafiero, V. H., from Atlanta to Eatonton, Ga.
Williams, R. F., from Richmond to Warm Springs, Va.
Williams, R. E., from Richmond to Hampton, Va.
Westervelt, J., from Housie Drug Store to 213 Main Street, Dallas, Texas.

LETTERS RECEIVED.

Asbby, A. A., Red Oak, Iowa.
Brown, E. V., Hebron, Ill.; Branch, G. H., Grand Isle, Vt.
Craue, A. M., Marion, Ohio; Cutler, J. A., New York, N. Y.; Cokenower, J. W., Des Moines, Iowa; Connor, L., Detroit, Mich.
Denison, C., Denver, Colo.; Dowling, Francis, Cincinnati, Ohio; de Schweinitz, E. A., Washington, D. C.; Dunn, I. J., Erie, Pa.
Egan, J. A., Springfield, Ill.; Engman, M. F., St. Louis, Mo.
Fox, J. F., New Philadelphia, Ohio; Fries, Bros., New York, N. Y.
Grant, T. P., Louisville, Ky.; Gihon, A. L., New York, N. Y.
Hummel, A. L., Advertising Agency, New York, N. Y.; Hektoen, L., Chicago, Ill.; Herrick, A. B., Santa Rosa, Calif.; Hance Bros. & White, Philadelphia, Pa.
Johnson, C. H., Grand Rapids, Mich.; Jackson, S. B., Pittsburg, Pa.; Jewett, J. H., Canandaigua, N. Y.

Wilbur, C. T., Kalamazoo, Mich.

PAMPHLETS RECEIVED.

Abdominal Surgery, Some Remarks and Reports upon Specimens in. By H. O. Walker, Detroit, Mich. Reprinted from Physician and Surgeon.
Alcoholic Epilepsy. By C. H. Hughes, St. Louis. Reprinted from Alienist and Neurologist.
Bacteria, Procedures Recommended for the Study of, the report of a committee of American bacteriologists to the Committee on the Pollution of Water-supplies of the Amer. Public Health Ass'n. Paper, pp. 47, Concord, N. H.: The Kniford Press. 1898.
Colles Fracture and the Roentgen Rays; A New Operation for Balanic Hypospadias; The Radical Treatment of Carbuncle; Ueber den diagnostischen Werth der Roentgenstrahlen bei der Arteriosklerose. By Carl Beck, New York City. Reprints.
Crookes' Tubes; a Possible Step Toward Maximum Radiance, a Preliminary Report on a Method of Overcoming High Resistance in. By Wm. W. Graves, St. Louis. Reprinted from American X-Ray Jour.
Commercial Spirit and Some of Its Influences, the. By Q. Cincinnati Smith, Austin, Texas. Paper, pp. 10.
Galvanization and Galvano-Faradization. By A. D. Rockwell, New York City. Reprinted from N. Y. Med. Jour.
Heart Complications in Diphtheria. By Cleon Melville Hibbard, Boston, Mass. Reprinted from Boston Med. and Surg. Jour.
Injuries from "Live" Electric Light and Trolley Wires. By J. J. Brownson, Duquque, Iowa. Reprinted from Tri-State Med. Jour. and Prac.
Kryofin, a Clinical Study of. By Sidney V. Haas and J. Bennett Morrison, New York City. Reprinted from N. Y. Med. Jour.
Medical and Psychologic Aspects of the Luetgert Case, the. By J. Sanderson Christison, Chicago. Reprinted from Chicago Law Journal.
Morphin and other Drug Habits. By C. E. Patterson, Grand Rapids, Mich. Reprinted from Medical Summary.
Normal Salt Solution in Medicine and Surgery. By Palmer Flindley, Chicago. Reprinted from Medical Standard.
Quinin in Malarial Hemoglobinuria, the Use of. By Albert Woldert, Philadelphia. Reprinted from Medical News.
Vaginal vs. Abdominal Operations, Principally for Pus in the Pelvic by Joseph Taber Johnson, Washington, D. C. Reprinted from Am. Gyn. and Obstet. Jour.
Wirkungswiese des kohlensauren und des calicysauren Natrons bei Gicht, Rheumatismus und der Harnsaureausscheidung. By Dr. Mordhorst, Vienna. Reprinted from Centralblatt für Innere Medizin.
Yellow Fever, Prevention of, and the Quarantining of Houses to Stamp It Out. By Stanford E. Chaillé, New Orleans, La. Reprinted from N. O. Med. and Surg. Jour.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from May 28 to June 3, 1898.

Acting Asst. Surgeons Francis M. C. Usher and E. A. De Lipesey, U. S. A., will proceed to Key West, Fla., and report in person to Major William R. Hall, surgeon in charge of the general hospital at that place, for duty.
Acting Asst. Surgeon C. L. G. Anderson, U. S. A., will proceed from Hagerstown, Md., to Newport News, Va., and report for duty with Light Batteries A and C, Pennsylvania Volunteers.
Acting Asst. Surgeon Burke L. Johnson, U. S. A., will proceed from Kenton, Ohio, to Ft. Thomas, Ky., and report for duty in the general hospital at that place.
Acting Asst. Surgeon Walter Whitney, U. S. A., will proceed from Chicago, Ill., and report in person to the commanding officer, Ft. Sheridan, Ill., for duty at that post.
Major George H. Torney, Surgeon, is assigned to duty in command of the hospital ship "Relief."
Acting Asst. Surgeon S. Melville Waterhouse, U. S. A., is relieved from duty at Ft. Hamilton, N. Y., and ordered to Ft. Myer, Va., for duty in general hospital at that place.
Major Robert H. White, Surgeon, order assigning him to duty with the Philippine expedition is revoked.
Major Louis W. Crampton, Surgeon, will proceed to Tampa, Fla., and report in person for duty to Major-General William R. Shafter, U. S. Vols., commanding the Fifth Army Corps.
Major Valery Havard, Surgeon, will proceed to Tampa, Fla., and report in person to Major-General Joseph Wheeler, U. S. Vols., commanding the cavalry division at that place, for assignment to duty as chief surgeon.
Acting Asst. Surgeons A. R. Booth, Joseph A. Tabor and T. S. Dabney, U. S. A., are relieved from duty at New Orleans, La., and ordered to Tampa, Fla., for duty with U. S. troops at that place.
Acting Asst. Surgeon Robert E. Williams, U. S. A., will proceed from San Francisco, Cal., to Angel Island, Cal., and report for duty; he will also render medical attendance to the garrison at Ft. Baker, Cal.
Acting Asst. Surgeon W. Hoefner Winterberg, U. S. A., will proceed to Alcatraz Island, Cal., and report for duty.
Acting Asst. Surgeon John B. Darling, U. S. A., will proceed from St. Paul to Ft. Snelling, Minn., and report for duty.
Capt. William P. Kendall, Asst. Surgeon, is relieved from duty at Ft. Brown, Texas, and ordered for duty with Ninth Cavalry in the field at Tampa, Fla.
Capt. Henry A. Shaw, Asst. Surgeon, is relieved from duty at the brigade hospital in the field at Tampa, Fla., and ordered for duty in general hospital, Key West, Fla.
Acting Asst. Surgeon A. H. Mann, U. S. A., will proceed from Springfield, Ill., to Key West, Fla., and report for duty in general hospital at that place.
Acting Asst. Surgeon Ezequiel de la Calle, U. S. A., will proceed from Washington, D. C., to Tampa, Fla., and report to the commanding General Seventh Army Corps for assignment to duty.
Major Phillip F. Harvey, Surgeon, will proceed to Tampa, Fla., and report in person to Major-General William R. Shafter, commanding the Fifth Army Corps, for assignment to duty as chief surgeon of one of the divisions of that corps.
Capt. John L. Phillips, Asst. Surgeon, is relieved from duty at Ft. Walla Walla, Washington, and ordered to Alcatraz Island, Cal.
Capt. Thomas O. Raymond, Asst. Surgeon is relieved from duty at Ft. Canby, Washington, and assigned to duty with the expedition to the Philippine Islands.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, JUNE 18, 1898.

No. 25.

ORIGINAL ARTICLES.

THE DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF PULMONARY ABSCESS AND GANGRENE, WITH VIEW TO SURGICAL TREATMENT.

Read at the Forty-eighth Annual Meeting of the Illinois State
Medical Association, Galesburg, Ill., May 18, 1898.

BY ROBERT H. BABCOCK, M.D.

Professor of Clinical Medicine and Diseases of the Chest, College
of Physicians and Surgeons.
CHICAGO, ILL.

In dealing with the pulmonary diseases to be considered in this paper the surgeon is confronted with the following questions: 1. Is the affection in reality abscess or gangrene of the lung? 2. Can the focus be reached and should it be operated on? 3. Are the pleural surfaces overlying the affected part of the lung adherent? A correct answer to these queries requires fine diagnostic ability at all times, while it not infrequently baffles the diagnostician altogether.

To answer the first query requires a differential diagnosis between abscess and gangrene on the one hand, and on the other, the differentiation of these from the following conditions: an abscess of some adjacent structure, as of the liver, that has ruptured into the lung; an encysted empyema; an echinococcus cyst of the lung; bronchiectasis; fetid bronchitis and pulmonary tuberculosis. I shall not deal with hepatic or other abscess perforating the lung; previous history and symptoms ought ordinarily to guard against mistaking it for an original pulmonary affection.

In attempting to distinguish abscess from gangrene one should not only remember that they have much in common as regards causation and symptomatology, but also that in some cases a sharp dividing line can not be drawn. The recognition of a local lung destruction, gangrenous or otherwise, depends not alone on physical examination of the chest. Indeed, in some cases this may furnish less information than do the history and symptoms. Thus may be discovered a pyemia, a puerperal septicemia, or some distinct localized infection, which, by throwing light on the etiology, may materially assist in a correct interpretation of the symptoms and physical signs of the chest affection. The patient may be found to have been intemperate and to have just had croupous pneumonia, or a child may have aspirated a foreign body into his lungs, or there may be an erysipelas, and quinsy and the like to serve as a probable cause of subsequent pulmonary infection. I recall a man in the Cook County Hospital who died of multiple pulmonary gangrene resulting from an old middle ear abscess that had led to pyelo-phlebitis of the right internal jugular vein.

There are four cardinal symptoms alike of pulmo-

nary abscess and gangrene: pain in the affected lung, dyspnea, cough and fever. These are not distinctive, as they may all be present in purulent pleurisy. It may be said however, that in pulmonary abscess and gangrene thoracic pain is likely to be more persistent and severe, since, with the on-coming of effusion the pain of pleurisy often abates, even when it does not cease. Moreover, if the abscess be of embolic origin, it is announced by sudden sharp pain at the seat of the embolus. In hydatid cyst of the lung, on the other hand, pain may be a marked feature. Upon rupture of a pulmonary abscess into a bronchus there is generally agonizing pain, accompanied or followed by violent cough that ushers in the expectoration of pus, but identical phenomena attend the rupture of pus into the lung from a hepatic abscess or from the pleural cavity. With the evacuation of the abscess pain diminishes or ceases.

Dyspnea is a variable symptom, depending on the extent of lung involved and associated pleurisy, and possesses no characters peculiar to this affection. It may be shallow and hurried in consequence of intensification of pain when respiration is slow and deep; or breathing may be labored and difficult. In brief, this symptom may be said to denote some pulmonary embarrassment, but not its nature or location. Cough is a symptom of great importance, since it likewise points to lung disease, but it possesses no characters pathognomonic of abscess. In general it may be said to be more severe and paroxysmal than that of empyema and phthisis but not of bronchiectasis and gangrene, in which last-named affection it also racks the sufferer intolerably. The fever is that of sepsis, depending in its *minima* and *maxima* upon the kind of micro-organisms concerned in its production. For the most part its extremes are of wider range and its type more irregular than in either of the other affections excepting gangrene, while in bronchiectasis pyrexia may be absent. It is almost needless to remark that accompanying the irregularly intermitting fever are more or less pronounced rigors, sweating and loss of both weight and strength, all of them phenomena of grave constitutional infection.

So long as the abscess contents remain confined within the lung the sputum is of negative value and there is nothing in the symptomatology to denote the character of the inflammatory process occasioning it. So soon, however, as rupture into a bronchus occurs the characters of the expectoration assume the greatest importance. If it be a suppurative pleuritis or an abscess of some adjacent structure that has broken through into the lung, the sputum will, except immediately following the rupture, consist of pus without pulmonary tissue: whereas, if an abscess of the lung has ruptured, elastic fibers and fragments of pulmonary tissue will be mingled with the pus. The color is yellow or yellowish-green and there is generally no odor.

If the condition be gangrene and not abscess, the characters of the expectoration are very striking and different. Its most impressive feature is its almost unendurable fetor, alike distressing to patient and attendants. This may be of an indescribably sweetish character or it may be that of decomposing blood, or mingled with the stench of putridity is a fecal odor. It is most intense during the act of coughing, although the patient's breath is contaminated by it at all times, as is the atmosphere of the sick-room. The sputum has a dirty gray or brownish or brownish-green color and when allowed to settle in a glass divides into three layers. The uppermost consists of froth of the characteristic hue and contains mucus; the middle one is serous, transparent and albuminous; while the bottom layer, thick, greenish-brown, contains masses which horribly fetid consist of shreds of pulmonary tissue. According to Leube, elastic fibers are only present when the sphacelated parenchyma has been expectorated before the peptic ferment, shown to be present by Filehne and others, has had time to dissolve them. But even when elastic tissue is absent the microscope detects fibers having the characteristic alveolar arrangement. In addition, this bottom layer contains disintegrated blood cells, oil drops, hematin crystals, pigment granules, crystals of the triple phosphates and the various fatty acids, Dittrich's plugs, leptothrix and numerous micro-organisms.

A reliable diagnosis of pulmonary gangrene can only be made by a microscopic examination of the sputa, since a similar fetor of the breath may be detected in cases of bronchiectasis and fetid bronchitis. Even in these affections shreds of lung tissue may appear in the sputa when under the influence of decomposition of the retained secretions the bronchial walls soften and break down and the adjacent parenchyma becomes a prey to the necrotic process. In such instances a differential diagnosis is extremely difficult, if not impossible, and one must be guided largely by the history and duration of the malady. It might well be in such cases that the patient's emaciation and prostration would not have reached so extreme a degree as would exist had his ailment been gangrene from the start.

From the foregoing, it is seen that so long as expectoration is wanting the symptomatology of abscess and gangrene is practically the same (except that the latter often runs a much more rapid course) and that it is often impossible to establish the diagnosis prior to rupture and discharge through the bronchi. Some etiologic factor, as pyemia or the aspiration of a foreign body, may render the existence of one or the other disease likely and suggest which of the two it is, but the character of the sputum alone can determine the diagnosis.

Although the physical signs are of great importance and should never be neglected, they can not be relied on to clear up the diagnosis before the establishment of expectoration. These are the following: Dulness over a circumscribed area of variable size, provided the seat of lesion is not deeply situated, is single and large enough to alter the percussion note. If a cavity becomes established and other conditions are favorable the note is tympanitic. Upon auscultation the breath sounds are found to be bronchial, or if the area has broken down but not yet ruptured and evacuated, they will be suppressed, while the transmission of vocal fremitus is correspondingly altered. Râles over the affected area are usually wanting during this

period. Should the focus be sub-pleural, the auscultatory phenomena of fibrinous pleuritis are likely to be added. If croupous pneumonia have preceded, there will have been signs of this affection.

It is now necessary to consider the diagnosis of cavity, inasmuch as the surgeon in dealing with abscess or gangrene has to be familiar with the means of determining when it has formed. To this end percussion is chiefly to be relied on, yet certain conditions are indispensable if percussion is to avail anything: 1, the vomica must have attained a sufficient size, at least that of a walnut; 2, solidified lung tissue must supervene between it and the surface percussed; 3, the cavity walls must possess sufficient resistance and smoothness to reflect the vibrations communicated to them; 4, the waves of air produced must have sufficient amplitude to produce the overtones essential to tympany.

If these conditions be fulfilled, percussion over a cavity will elicit tympanitic resonance, the pitch of which depends upon the length and number of the vibrations within the cavity. But other conditions than a vomica can give rise to this kind of resonance, as for instance, when cracked-pot resonance is produced by strong percussion of a child's chest in case of bronchitis. Wintrich suggested as diagnostic the change of pitch observed under favorable circumstances when the patient closed his mouth during the act of percussion. That is, when the vomica communicates freely with a bronchus, the pitch of the percussion note is perceptibly higher with the mouth open than with it shut. This, however, is not absolute and therefore Gerhardt's change of pitch was proposed as a diagnostic test. This consists of an alteration of pitch depending on the patient's position; if the cavity be longer in one direction than another and it contains fluid, change the patient's position, as from the recumbent to the erect or *vice versa*, will, through gravitation of the contents to the bottom of the vomica, correspondingly elevate the pitch of the percussion note. Either the Wintrich or the Gerhardt change of pitch is ordinarily proof enough of the presence of a cavity, but if the diagnostician is still captious, he may seek for the so-called interrupted Wintrich change of pitch. That is, when with the mouth open a rise of pitch in the percussion note is detected only in a certain position, as the recumbent, but not in the sitting posture. An elevation of the pitch during slow inspiration over that during expiration is also a sign of cavity, but of all of these none is held to be pathognomonic except the interrupted Wintrich change of pitch. In addition to the foregoing is that peculiar quality of note known as cavernous and amphoric, which must have been heard to be recognized, since it can not be described.

Upon auscultation of a vomica there may be heard bronchial, cavernous or amphoric breathing, which does not require more than mention. Likewise, there are the cavernous or amphoric voice and certain râles. Of these last the most significant are the gurgles or bubbling râles heard during inspiration, and the metallic tinkle of Laennec. A conjunction of two or more of the signs just mentioned may, in a given case, establish a diagnosis, although none of them be pathognomonic.

Finally, a differential diagnosis must be made in this early stage between a suppurative inflammation of the lung and circumscribed empyema. To this end the previous history and symptoms must largely contrib-

ute, owing to the similarity of the physical signs. The problem is rendered still more difficult by the following considerations: Abscess is a relatively frequent result of lobar pneumonia, while circumscribed pyothorax is often found complicating this form of pneumonia. The pneumococcus gives rise to a pleuritic exudate rich in fibrin and hence it becomes readily encysted. It is generally circumscribed within the confines of the lobe affected with the pneumonia, sometimes occupying the whole, but more often a part of this area, and through the failure of the dull patch to clear up after the crisis it may give rise to the belief that resolution has not taken place. Should this collection of pus, circumscribed under great pressure, at length break through into a bronchus, it is very apt to be mistaken for abscess. It should be remembered however, that pulmonary abscess generally occasions far greater constitutional disturbance; fever is higher and more distinctly septic; rigors are more pronounced and perspirations more intense; the patient's strength and weight decline more rapidly, and what is more important, local pain and cough are usually more severe. Pus produced within the pleural cavity by the pneumococcus is rather benign in character and unless mixed with strepto- or staphylococci, occasions only symptoms of mild infection. When, however, admixture with pyogenic organisms takes place, the pus becomes correspondingly more virulent and septic phenomena proportionately greater.

The importance of the information derived through physical exploration of the chest will depend upon the amount and depth of the exudate. If this be sufficient to threaten rupture, there is likely to be more or less evidence of pressure. Careful inspection and palpation will detect slight filling or smoothing out of the intercostal spaces over the affected area, and the side is apt to show slight elevation of the ribs, thus giving a little more rotundity to that part of the thorax. If the exudate compress the lung to an appreciable degree, the apex beat will generally be displaced, although accurate observation is often required for its determination. In my experience, an exudate of this kind is rarely massive enough to occasion appreciable displacement of the liver. Particularly careful study of the pectoral fremitus, and of the breath sounds, as recommended by Potain, will often furnish valuable differential information. I have repeatedly detected feeble vibration, extending into the distinctly dull zone, and being absent only over the very center of dulness, seeming thus to indicate a gradual increase in depth of the exudate from periphery to center. Such would not be the case in abscess and gangrene, for pectoral fremitus is usually exaggerated over the affected focus, during the inflammatory stage, and after evacuation, but absent after the lung substance has broken down, and before evacuation. In empyema, upon percussion, dulness is generally found to shade off gradually into resonance, the transition being less abrupt than in abscess. Upon auscultation the breath sounds may be either inaudible or, in case the exudate be not too deep, enfeebled and bronchial. In some instances, I have detected a vague friction sound about the edge of the dull patch, while in others, it has been rather an indefinite impression of a rubbing of rough surfaces rather than actual friction sounds.

Should the pent-up pus of empyema at length find exit through the bronchi, the event may be correctly interpreted by examination of the sputum, which as

already stated does not contain elastic tissue except at the very beginning of or soon after the onset of the perforation. The physical signs will then become those of a cavity, and if the case be then seen for the first time, a differential diagnosis may be extremely difficult or impossible. The percussion note is tympanitic, and the respiratory sounds tubular or even amphoric, and moist râles or perhaps metallic tinkling may be heard. The loud and whispered voice-sounds should be carefully studied, for, unless the communication with the air-passages be very free, they would hardly be such as are heard over vomicae of such dimensions. In the event of a failure of differential diagnosis, and the amelioration of symptoms that ensues renders surgical interference unnecessary, the subsequent history will probably clear up the doubt. In case of empyema, convalescence is more rapid and steady.

The differential diagnosis between pulmonary abscess and tuberculosis with formation of vomicae is easy, although it must be borne in mind, as stated by Leube, that the seat of suppuration following pneumonia is most frequently the upper lobe. In consumption generally, the history and symptoms indicate a chronic disease, but it should be a case of acute pneumonic phthisis, with rapidly forming cavity, the detection of tubercle bacilli in the sputum, together with disintegrating lung tissue, will settle the diagnosis.

One of the most difficult tasks is to differentiate between pulmonary abscess and bronchiectasis, or in some instances between gangrene and bronchiectasis with fetid bronchitis. Here again as always, the anamnesis is of the utmost importance, pointing in the one case to an acute, while in the other to a chronic malady. Moreover, only very exceptionally are elastic tissue fibers, having an alveolar arrangement, present in the expectoration of bronchial dilatation, and when these do occur, the case has been converted into one of abscess to all intents and purposes, and may be treated as such. Not often does bronchiectasis present conditions favorable for diagnosis in respect to determining its operability. Its existence may be strongly suspected from history and symptoms, such as chronicity of the malady, the violent, spasmodic cough and thick muco-purulent sputum that is sometimes most readily expelled in certain positions and does not contain pulmonary tissue, etc., but it may be quite another matter to accurately locate the cavity, and to state whether more than one exists. As a rule, bronchiectases are multiple, and surgeons of experience like Dodlee assert that operative interference is successful only when a single, large sized dilatation exists at the base of the lung. In such a case, the physical signs are those of a cavity from any other cause, and have already been considered. A very significant sign of bronchiectasis is the detection of tympanitic resonance over a circumscribed area which prior to cough and expectoration presented dulness, and where bronchial breathing then replaces former absence of respiratory sounds.

The only disease remaining, from which pulmonary abscess must be differentiated, is echinococcus cyst of the lung. Pain in the affected side, sometimes very intense, severe and spasmodic cough and prostration are also present. Dulness does or does not exist only as the cyst is superficial or deep seated. In the latter event, there may sometimes be heard dis-

taut, numerous crackling râles over a considerable area. If suppuration be set up roundabout the cyst, sepsis may supervene and abscess be still more closely simulated. The one diagnostic feature is the expectoration of a thin, serous fluid containing the characteristic rolled up membranes, or hooklets. Morillon states that the diagnosis is confirmed, even before this pathognomonic expectoration, by the appearance of urticaria during the course of this obscure affection. Fortunately hydatid cysts are very rare in this country.

Supposing that abscess or gangrene either before or after cavity formation, has been satisfactorily determined to be present, the question arises, is the condition operable? This depends on its etiology and location. If it be pyemic in origin, operation will probably prove of but little avail since other foci than that operated on may be scattered through the lungs. On the other hand, the abscesses most amenable to surgical treatment are those resulting from pneumonia, and in general also, they are the most readily diagnosed. Unfortunately, experience has shown that even when a pus cavity has been located by physical signs, the operator may have much difficulty in reaching it with the exploring needle. This is said to be owing to the fact that a cavity usually lies higher than is supposed.

Lastly, arises the query, whether or not the pleural surfaces overlying the affected part be adherent? If the seat of pulmonary inflammation be directly underneath the pleura, or if in the course of the disease pleuritic friction sounds have been detected in said area, then adhesion of the pleura may be strongly suspected. But more than this can not be affirmed in the present state of our knowledge.

I will now briefly describe a few cases that illustrate some of the difficulties encountered in the diagnosis of the affections under discussion:

Case 1.—In the very beginning of my practice I attended a young woman with pneumonia of the middle lobe of the right lung. After a few days her sputum became very copious, of a brownish red color and of the characteristic odor of decomposing flesh or blood. It was not examined microscopically, but as not many days subsequently a small zone of tympany developed at the lower edge of dulness, I concluded that gangrene had set in. My diagnosis seemed confirmed by the continuance of the fetid sputa, the septic symptoms and above all the gradual spreading of marked tympany, until at length it involved the entire area of original dulness. Convalescence now set in slowly and progressed until the patient was able to get about, although with troublesome cough and considerable purulent expectoration. The middle lobe now presented the following signs: Pronounced tympany, bronchial breathing, that could be plainly heard behind, pectoriloquy, some moist râles, and more than all, distinct bulging of the intercostal spaces in this area upon coughing. This last seemed to leave no room for doubt of the existence of a cavity. Dr. Christian Fenger concurred in the diagnosis, and a few days later operated by the means of the actual canterbury. Two or three days subsequently the patient died, and the necropsy revealed, not a vomica, but multiple racemose bronchiectases throughout the entire area over which signs of a vomica had been erroneously thought to exist. This showed that the bulging of intercostal spaces during the expiratory pressure of coughing can not, as supposed by the late Austin Flint, be considered diagnostic of cavity.

Case 2.—This was a female patient in my service at Cook County Hospital five or six years ago. I made a diagnosis of diaphragmatic empyema at the base of the left lung, following pneumonia. Dr. Holmes operated, but instead of empyema found multiple small abscesses containing a cheesy material, and scattered along the base of the lower lobe from front to back, close to the diaphragm. At the time he looked upon these as tubercular, but I now conjecture that they were multiple abscesses, such as sometimes form in the course of broncho-pneumonia. The patient made an uneventful recovery.

Case 3.—Some years ago I was asked to see an elderly man who had passed through a recent croupous pneumonia, which was thought not to have resolved, but to have resulted in an abscess that had ruptured into a bronchus. He had had a low septic fever with harassing dry cough, and the day before my visit had suddenly begun to cough up pus.

Signs of a cavity had appeared at the right base, below the scapula. After careful examination of the chest and due consideration of the previous history and symptoms, I made a diagnosis of an encysted empyema, which had broken through into the lung, and advised operative interference. This was carried out, and in so doing the correctness of my diagnosis was determined.

Case 4.—Not far from that time, I saw another man, who had just passed through a lobar pneumonia that was thought not to have properly resolved, but to have resulted in abscess. A mild septic temperature persisted, with troublesome cough, and a zone of dulness over which breath sounds were absent, remained at the right base, behind. I diagnosed encysted empyema and advised an operation, which was done. Upon the surgeon's having entered the pleural sac slightly too far to one side, and having failed to find pus, he introduced his finger and felt the abscess wall, which seemed to him to bulge from the surface of the lung into the pleural cavity. He thereupon passed his instrument along his finger as a guide, and opened the supposed abscess from a little below and anteriorly. As he did so, air escaped with the pus. Therefore, he naturally concluded that my diagnosis was an error. Fortunately, however, I had requested to have a specimen of the pus obtained brought to me, and microscopic examination of this specimen showed an entire absence of pulmonary tissue. Obviously there was but one conclusion, that the lung had been perforated simultaneously with the penetration of the empyema. Both these last patients made a satisfactory recovery.

Case 5.—About a year ago Dr. Bayard Holmes asked me to see an elderly man who complained of pain in his left chest, behind near the region of the kidney. There was a history of an obscure affection that had been diagnosed about a year previously as abscess of the spleen. Two or three months prior to my seeing the patient, Dr. Holmes had made an exploratory incision over the left kidney and found it healthy; at the same time, all the abdominal organs were palpated by laparotomy and found normal. Examination of the lungs disclosed a dull area, with bronchial breathing and faint friction-like râles at the extreme base of the left lung, extending from the vertebral column, forward nearly to the posterior axillary line. A positive opinion was not given, but as the patient had a mild pyrexia, I concluded a thin layer of not very infective pus was encysted in the

pleural cavity and advised operative measures for the man's relief. Dr. Holmes subsequently reported that he found an aneurysm of the descending aorta that compressed the base of the lung. The interesting feature of the tumor was, that it did not pulsate and was so firm that it was not recognized until the doctor inserted a hypodermic needle and withdrew blood. The aneurysm had begun to erode the vertebrae. The patient lingered for a few weeks and died of rupture of the aneurysm.

103 State Street.

A UNIQUE CASE OF PERINEO-SUPRAPUBIC SECTION.

BY G. FRANK LYDSTON, M.D.

Professor of Genito-Urinary Surgery and Syphilology in the Medical Department, Illinois State University; Major and Surgeon, Second Illinois United States Volunteers, etc.
CHICAGO, ILL.

Through the courtesy of Drs. Griffith and Ryan of St. John's Hospital, Springfield, Illinois, I had the opportunity of operating a few days since, upon a most interesting case. A man 45 years of age, occupation mechanic, sustained a fall upon his perineum some nine years ago. This was followed by urethral hemorrhage, with considerable swelling and ecchymosis in the perineal region. Retention of urine occurred, and the catheter was used for some days. A few weeks after the injury the patient noticed that his already lessened stream of urine was rapidly diminishing in size. The contraction of the urethra continued until complete retention recurred. The catheter was again resorted to, and, satisfied with temporary relief, the patient did nothing in the way of treatment until another attack of retention came on. This was treated as the other attacks had been, and with equal success. During the many years since the original injury the patient has experienced a number of attacks of retention, and has been treated by sounds at intervals. On various occasions considerable hemorrhage resulted from the passage of the sounds. The contraction of the urethra finally became so marked that more or less constant dribbling of urine from overflow resulted.

Examination showed a well nourished man of fairly good physique. The bladder was not distended with urine, although dribbling from the meatus was almost constant. The condition of the patient's clothing and the ammoniacal odor about him showed that this was of by no means recent development—an inference corroborated by the history. The prostate was apparently normal. Exploration showed the urethra to be free from contractions until the bulbo-membranous region was reached, at which point a firm fibrous contraction was noted. This proved to be impermeable to instruments. Had time permitted, however, it is probable that a filiform guide might have entered. The perineum was hard and somewhat swollen, peri-urethral inflammation, probably from slight infiltration, had perhaps occurred.

Perineal section was proposed and consented to.

Operation: Chloroform was used, as is my custom in long-standing cases of obstructive surgical disease of the urinary tract. After flushing the urethra with a 1-20,000 bichlorid solution, a grooved staff was passed down to the face of the stricture. The urethra was then opened in front of the obstruction, and a search for the opening in the stricture begun. The membranous urethra was found to be completely

obliterated, the bulb being encroached upon and contracted for about an inch anterior to the bulbo-membranous opening. After a careful dissection, occupying fully three-quarters of an hour, the cicatricial tissue was divided, and my index finger apparently entered the urethra and penetrated the bladder. I could plainly feel the vesical rugae, and the grip of the characteristically hypertrophied false sphincter vesicae found in such cases. Much to my surprise, however, no urine escaped, nor could I detect fluid with the exploring finger. Suspecting that I had entered an old, false passage, I began a fruitless search for the normal canal, lasting probably half an hour. It has been my custom of late years, in such cases, to refrain from a too prolonged and dangerous search for the urethra in the perineum. I believe that suprapubic section and retrograde exploration with the finger or catheter does not greatly complicate matters, nor does it add much to the dangers of the operation. Prolonged anesthesia and hemorrhage are the elements of the operation that are most to be dreaded. These can be avoided by suprapubic section. In accordance with this view I entered the bladder above the pubes. I found the viscus very slightly distended with urine. I punctured the bladder well down toward the vesical neck, making an opening only as wide as the blade of the medium-sized scalpel I was using. I inserted a pair of forceps into the puncture, and, opening them, stretched the wound sufficiently to admit my left index finger. There was little trouble in dilating and exploring the vesical neck from within. On opposing the intra-vesical and perineal index fingers I found, as I had suspected, that I had entered a blind false passage. The thin lining of this canal covered my finger like the finger of a glove, and through it I had felt the rugae of the vesical walls. After restoring the continuity of the urethra and laying the two canals into one, I proceeded to still further divide all the cicatricial tissue detected by the finger in the perineum. In accomplishing this an old peri-urethral abscess sac was discovered, containing eight small phosphatic calculi. This sac was thoroughly laid open.

The perineal wound was drained by a large firm rubber tube, about which iodoform gauze was tightly packed to check hemorrhage. No attempt was made to close the bladder wound. The suprapubic incision was almost entirely closed by catgut and silkworm gut sutures. A single narrow strip of gauze was pushed well down into the cavity of Retzius, no other provision for suprapubic drainage being made. The subsequent course of the case was uneventful. The temperature rose but very slightly. Perineal drainage was perfect; not a drop of urine escaped through the suprapubic wound, which healed by first intention, the gauze drain being removed on the fifth day, at which time the perineal tube was also removed.

The technique and results of the combined section in this case are worthy of note. The ideal healing of the suprapubic wound in the face of infection from the bladder was remarkable, though I have seen a number of similar results. The danger of leakage where the method adopted in this case is followed is practically nil. It is unnecessary and unwise to suture the bladder in such cases. Leakage can not occur unless the bladder becomes distended—which it never does if perineal drainage is free. A vesical opening that will readily admit the finger is difficult to find in the collapsed bladder. As a cardinal prin-

ciple, therefore, vesical exploration and operations should involve as little cutting as possible. This is wise even where stones are to be extracted.

Once the technique of suprapubic section has been mastered, the surgeon need not dread perineal section without a guide. There can be no justification, moreover, for a prolonged and dangerous perineal search for a lost urethra. In intensely septic cases, through and through drainage is advisable.

The rationale of the stone formation in the foregoing case is simple. Decomposing residual urine in an old peri-urethral pus cavity explains it. The false passage was probably of "surgical" origin, and had deluded several surgeons into the belief that they were successfully dilating the stricture. Such errors are by no means rare.

Camp Tanner, Springfield, Illinois.

PERINEAL OPERATION FOR PERFORATIVE APPENDICITIS WITH ABSCESS IN THE CUL-DE-SAC.

Read before the Peoria Medical Society, May 3, 1898.

BY E. M. SUTTON, M.D.

PEORIA, ILL.

The literature on the surgical treatment of appendicitis is replete, and it is the consensus of opinion that, for ordinary cases of perforative appendicitis with abscess formation the incision over McBurney's point, or the extra-peritoneal operation from the side, reaching the abscess without entering the peritoneal cavity, with simple evacuation and drainage, only removing the appendix when possible to do so without causing general infection, are the best methods of procedure.

In looking over the reports of cases it has not come to my knowledge that an operation reaching the appendix abscess, when located back of the bladder, below the small intestine, and in front of the rectum, has been operated on from the perineum. The difficulties of draining these cases through the abdominal incision and the avoidance of soiling the peritoneum are barriers which render the operation useless and fatal when attempted above, except when the operation is made before perforation or before any large quantity of pus has formed.

When the appendix lies externally or behind the caput coli the operation for appendicitis becomes quite simple, and those are the cases which encourage the physician to become a surgeon. But when the appendix lies internal to the caput coli, above the mesentery of the small intestine, the most skilled operators may have grave fears of the result. When the appendix lies below the mesentery of the small intestine, internal to the caput coli and perforation occurs, abscess forms, pressing on the rectum or the bladder. When the small intestine forms the upper wall of the abscess and the tendency of the case is toward rupture into the bladder or rectum, or both, with long-continued illness, never closing abscess sac or sinus, in some cases recovery may take place, or in others, death may follow from general peritonitis. It is not the diagnosis of appendicitis alone, which every skilled physician should be able to make, but the locating of the appendix, which marks the skilled surgeon, as upon this point the success of any given operation may depend.

By the following I wish to point to the possibilities of diagnosing the appendix perforation with

abscess formation, in the somewhat unusual place, the pelvic cavity of the male, and also the advantage of reaching the same extra-peritoneally, from the perineum.

Mr. F. A., age 35, locomotive fireman, stout build, perfect health, on the evening of March 16, after drinking a glass of milk and eating a light lunch in a restaurant, was suddenly seized with pain that was referred to every place over the entire abdomen. Returning home, a distance of ninety-three miles, a physician was sent for and gave him the proper treatment for appendicitis. The pain, locating itself along the lower part of the abdomen, over the symphysis, was continuous and extreme. The bowels responded to saline cathartic. The pulse was 100, temperature 100 to 102 degrees. March 19, third day of the attack, examination of the patient revealed a tumefaction high up in the median line and to the right of the rectum. There was scanty urine, bowels responding to the use of salines, but greatly distended. There was profuse perspiration, pulse 96 to 100, temperature 100.

Having had sad results from operations for appendicitis through the median line for this class of cases when seen late, I counseled delay, as perforation had taken place, and, with distension so great, the removal of the septic debris would undoubtedly end fatally if done in the usual manner while the pathologic condition seemed to be limited. Delay with hope of the abscess discharging per rectum was warranted. The usual line of treatment for appendicitis was instituted, the patient going to the second week, when the symptoms of obstruction, extreme pain, vomiting and great distension developed, with a serious septic condition. I evacuated the abscess through the rectum, high up, puncturing the anterior wall into the cul-de-sac with a small trocar. This I knew to be unsurgical, but the symptoms were desperate and demanded instant relief. Twenty-two ounces of foul pus were removed in this manner, its pressure having caused retention of urine and obstruction of the bowels. It was followed by an amelioration of the symptoms for two days, when, after a good night's sleep, the patient awoke with the most intense suffering, severe septic symptoms and complete retention of urine, the abscess having refilled and the symptoms decidedly worse. Pulse was 120, temperature 97 to 98 degrees, tongue dry and cracked.

An operation was performed through the perineum, to drain the abscess in that manner, making the horseshoe incision of Kocher, beginning at a point midway between the tuber ischii and the anus, extending to the bulbous portion of the urethra and from there to a similar point on the opposite side, separating the fat of the ischial fossa, pushing the external hemorrhoidal nerve and artery back, the transversus perinei, with the bulbous portion of the urethra and the superficial transverse perineal muscles forward. The transverse incision of the fibers of the external sphincter at junction with bulbo-cavernosus muscles was made and the division of the deep fascia transversely where it dips down to join the pelvic fascia, separating the levator ani muscles, reaching the prostate and continuing the dissection up back to the cul-de-sac. The abscess cavity was opened and nearly a quart of foul pus mixed with the liquid feces escaped. Washing with sterilized water and exploring with the finger, I found this

extensive cavity covered above by the intestines matted together, forming the upper abscess wall, with fundus at the caput coli. A drainage tube was inserted, and ordinary tamponing with iodoform gauze used. The pulse and temperature became normal, bowels moved six hours after the operation and patient's pain ceased immediately.

Subsequent history: Drainage was perfect, no further discharge after fourth day, no fever, no difficulty of bowel movements or bladder action. Temperature and pulse were normal five hours after the operation and distension disappeared immediately. Drainage tube was removed on the twelfth day. Wound granulated nicely. Patient fully recovered: out in third week.

In regard to the perineal operation for abscess of the appendix in this locality, the result was so satisfactory in this case that I have no hesitancy in advising the operation in case perforation and abscess formation takes place within the pelvis of the male, at the point described. In the female it is quite easy to reach an abscess of this kind requiring incision through the posterior cul-de-sac or between folds of broad ligaments, but in the male it is not so easily accomplished, yet can be done with perfect safety, and the great danger of causing general septic peritonitis and death by the usual operation can be avoided. The drainage being at the lowest point of the abscess, the intra-abdominal pressure completely evacuates it and the surgeon remains extra-peritoneal in all his procedures. The appendix could only be removed through the same incision if presenting and it would be impossible to take away more than the gangrenous portion. It is otherwise left to nature. The operator should have care not to break down the adhesions formed by the coils of the intestines forming the upper wall of the cavity, either by rough exploring or by too great force in washing it out.

The remarkable feature was the prompt closing of the perforation and healing of abscess, no fecal matter appearing after operation.

It might be asked if there was bulging of the perineum in this case that led me to incise here? While it was plain that fluctuation could be obtained by one finger high up in the rectum with counter pressure on the abdomen, not a sign of the collection could be obtained through the perineum and it seemed to those present that the proper method would be incision through the abdomen.

SURGICAL CLINIC IN GYNECOLOGY AT THE POST-GRADUATE SCHOOL OF CHICAGO, MARCH 7, 1898.

BY FRANKLIN H. MARTIN, M.D.,

PROFESSOR GYNECOLOGY,

ASSISTED BY F. A. BESLEY, M.D.,

INSTRUCTOR IN GYNECOLOGY,

CHICAGO, ILL.

[Stenographic report.]

Case 1.—The first case I have to present is one diagnosed fibro-myoma of the uterus. The patient is 45 years of age. She has borne no children. For several years there has been a menorrhagia developing, which lately has become excessive. Two suspicious symptoms about the case is the disproportionate loss of flesh in the last six months compared to the blood loss, and the almost universal fixation of the lower part of the tumor as I palpate it through the abdominal walls. It extends to just beneath the umbilicus. I should estimate the size of the tumor, including the uterus of which it seems a part, as eight inches in its long diameter, corresponding to the long

diameter of the patient, and the transverse diameter at the largest portion at four inches.

Exploratory Laparotomy.—I will make an exploratory laparotomy with the idea of removing the tumor if that course seems practicable. The assistants have thoroughly scrubbed the skin of the abdomen, first with soap and water with a soft flesh brush (the skin having been previously prepared by the nurses), then have washed it thoroughly with 95 per cent. alcohol, then with 1 to 1000 bichlorid solution, and finally rinsed with hot sterilized solution. Sterilized towels are placed around the field of the operation.

We make an incision from two inches below the umbilicus to an inch above the pubes. On opening the peritoneum with an incision about three inches in length we find a large tumor of the uterus presenting, resembling a fibroid, covered in different areas of its free surface with papillomatous growths. This form of growth extends into both broad ligaments, and on both sides in the region of the broad ligament, the space between the uterine tumor proper and the sides of the pelvis is filled with this peculiar wart-like growth. It is obvious that it would be impracticable for any one to attempt to remove this uterine tumor with the complete fixation which exists as a result of this material. The papillae extend onto the intestines, the mesentery and the omentum; they vary in size from that of an English walnut to that of a grain of mustard. The smaller ones resemble miliary tubercles. Without the microscope I will venture a diagnosis of adeno-carcinoma of the ovary with extensive direct continuity to the broad ligament and the fibroid uterus. The small piece of tissue that I secured on first opening the abdomen was immediately sent to the laboratory for examination.

Dr. Bethel, our pathologist, says, "I found it showed an adeno-carcinoma, papillomatous form."

I will close the abdominal wound without attempting the impossible—the removal of the tumor. Our prognosis must be of the most hopeless character. While the patient will probably recover from this exploratory operation, her lease of life will not extend, probably, beyond six months.

Case 2.—This woman is 37 years of age; married; has had three children, and two miscarriages. About three years ago she had an attack of peritonitis which followed "catching cold" after a miscarriage. This term catching cold is another term for infection. Infection, extending from vagina or cervix, which was present before the miscarriage occurred, or infection introduced by a careless obstetrician or midwife in attendance on the miscarriage, or it might have occurred as a result of the patient using a dirty douche point in attempting to cleanse herself after the miscarriage. Infection occurred and this was manifested by a high fever with rapid pulse, excessive pain in both sides in the region of the appendages, and considerable distention of the intestines.

This was undoubtedly caused by infectious material extending into the peritoneal cavity from the open ends of the Fallopian tubes. The immediate result of the leakage was a violent inflammation of the peritoneum at the point of infection. Fortunately, when this occurs at any point in the peritoneum the omentum, intestines and outlying peritoneum rushes in and attempts to limit the extension of the inflammatory action. This it ordinarily succeeds in accomplishing, and then the peritonitis remains local and runs its course in a few weeks, leaving the peritoneum with one or two pent-up pockets of pus. If this pus loses its virulence in the meantime, it may lie dormant for an indefinite time, and finally it becomes completely sterile. If the suppu-

ration is of a highly infectious character it will find an outlet through some of the adjacent organs, as the vagina, bladder, an intestine, or even the abdominal wall. In the case before us there is no history of an abscess having been discharged.

Symptoms.—This woman has been practically an invalid since her attack of ("inflammation of the bowels") peritonitis. She experiences excessive pain in the ovarian region almost constantly. The constant pain is of the character of pressure. Occasionally there are sharp acute pains in either side. She is never free from a severe backache. As menstruations approach the pressure symptoms and backache are greatly exaggerated. When the menstruation actually appears the woman suffers with excessive uterine cramp. As the flow is thoroughly established the pain becomes less. The woman, of late, has become excessively nervous. Her digestion is poor, and assimilation imperfect. She has headache, palpitation of heart, and frequently nervous spells in which it is with difficulty that she can control her will, and she becomes hysterical. These symptoms are all gradually increasing until she has become a despondent, suffering invalid.

Examination.—With the patient anesthetized, I proceed to make a bimanual examination with the finger of the left hand in the vagina and the right hand on the abdomen, I am able to palpate an irregular mass or tumor in the pelvis. With the cervix of the uterus fixed, I am able to trace what seems to be the uterus, about normal size, projecting backward into the Douglas cul-de-sac. From the sides of the uterus on both sides are large masses the size of a large orange on the right side, and of a smaller one on the left. Their large diameters, respectively, are three and a half and three inches. They are rather hard, but have the characteristic feel of tubal ovarian abscesses surrounded with adherent intestines. There are slight lines of demarkation between the masses and the uterus.

Operation.—From well-marked physical findings and symptoms, I am justified in performing a laparotomy. This I shall do with the idea of removing the diseased and destroyed appendages, and then fixing the uterus to the abdominal wall. As I incise the peritoneum the air rushes in and by that we can recognize the fact that we are in the abdomen. The intestines are full of gas, the patient not having been here long enough to be properly prepared. I immediately pack back the intestines with large gauze sponges, for three reasons: First, to keep them from being pinched or wounded during our manipulations; second, to protect them from any fluid which may escape during enucleation, in order that they may not become infected, and third, to protect them from being chilled because of exposure to the air of the room. With the bladder above, below and to the right we have a mass which seems almost inseparable from the intestines, and on the opposite side what seems to be a continuance of the mass.

The first thing to do is to locate the uterus, which is bound down in the posterior cul-de-sac and practically covered up. I go back of where the uterus should be and with the fingers gradually advance, posteriorly, until I reach the cul-de-sac of Douglas, using an unusual amount of pressure, of necessity, with these strongly adherent tissues. I now have the uterus well in hand, and passing off to the right and left, will endeavor to enucleate the appendages.

Going to the right and keeping well within the line of demarkation I gradually bring this large mass into view, but as I do so, because of its friability, it breaks and the fluid passes into the abdominal cavity and is absorbed by our protecting packs. In order that it will not gravitate beyond our packs into the abdomen we will lower the foot of the table a little. This enucleating is very difficult, and I can only liken it to the scooping out from the uterus of an adherent placenta.

We have finally brought up an infected mass, ovary, tube and broad ligament, from the right side, and from appearances it would not seem possible to successfully separate these tissues. I ligate the right broad ligament outside of this tumor deep enough to include the ovarian artery, in order to prevent excessive bleeding on this side. I now ligate off the tumor, which consists of a large cystic ovary filled with purulent matter, and a large adherent Fallopian tube. The ligature of catgut is made to include a pedicle near the right horn of the uterus. Now we start from the uterus again and pass off to the left side to begin enucleation of the appendages. It is almost impossible to get a starting point, and we must be careful not to penetrate an intestine. I have finally found a point from which I can begin my enucleation and am gradually getting the mass in hand and separating the adhesions. Here, posteriorly, is a large infected ovary and tube, very much like the opposite side, which accounts for the woman bearing no children since 1896. It is very seldom we see a double pyosalpinx so typically demonstrated. We tie off the mass the same as on the other side, including the round ligament here, in order to get a more stable pedicle.

I have the tube and ovary well up and will sever them close to the horn of the uterus, leaving nothing but the uterus. I disinfect the horn of the uterus thoroughly with strong bichlorid, and, before fixing the uterus to the abdominal wall, I will break up any further adhesions, getting a separation down into the cul-de-sac. I take a strip of tissue from the side of the wound, about three-fourths of an inch wide, and which contains the urachus, as a suspensory ligament for the uterus. With the uterus well up under the arch of the pubes I pass a Cleveland needle through its fundus, from behind forward, and draw the strip of tissue through this opening. Then, with a piece of catgut I secure the uterus to the peritoneal layer immediately above it, passing the catgut below the opening made by the Cleveland needle, which will act as a temporary stay until the uterus becomes fixed in the abdominal wall.

I have an enormous raw surface from which I enucleated these tissues, but adhesions of long standing bleed comparatively little, and there is less blood than you would expect. The peritoneum takes care of a large amount of blood and fluid of any kind if we can succeed in keeping it clean and antiseptic. I will put a glass tube into the cul-de-sac for the purpose of removing superabundant fluid and reducing the probability of infection to a minimum. You will be told by others, or read it in your books, that there is danger of the infection being carried from the exterior to the interior by means of the tube. This is impossible when the tube is properly cared for. We, who use the glass drainage tube, argue that it can do absolutely no harm when properly cared for. I have used it in hundreds of cases and no bad results followed,

and I know it may do an enormous amount of good. If you put in a tube, as a rule, the pulse will remain below 100, the skin will be moist, and you will have almost an ideal condition, simply because there is nothing left in the peritoneal cavity which can nurture bacteria, and without bacteria we can have no septic intoxication. The tube is dressed in one hour after the patient leaves the table. If there is less than two drams of fluid we increase the interval one hour, and continue to increase the interval one hour each time the wound is dressed if we get less than two drams, until we have increased the time to six hours, when, if we get very little fluid we will remove the tube. If, after the first two or three dressings, we get very little fluid the tube may be removed much earlier. In this case, we will probably be able to remove the tube by tomorrow morning.

I believe the results are better, in a case like this, to leave the uterus, when it is firmly fixed to the abdominal wall, than to remove it. I believe the bad results which frequently occur where the uterus is allowed to remain after the removal of diseased pus tubes are caused by the uterus being left in a retroverted position. If I should leave this uterus without fixing it forward, we would soon find it in retroversion, in which position it could easily become adherent, and we would have all the symptoms we usually get with a retroverted uterus. Ventral fixation of the uterus overcomes the objections, and we do not leave a vacuum, as when the uterus is removed, for the intestines to drop into.

In order that it shall not be necessary to open the whole wound in dressing the tube, place over the end of it a protecting dam, and this only will have to be opened when we dress the tube. The nurse who dresses it will take all the precautions to keep aseptically that she would in assisting at an operation.

Case 3.—Age 47; occupation, general housework. Family history: Mother died at age of 47; father died of tuberculosis; one brother and one sister living. Personal history: Menstruated when 14; always regular; never pregnant. Eight years ago she began to have trouble with her bladder, having pain when passing urine, which was worse at times; no other pelvic symptoms.

After a careful examination of this patient's pelvic organs, I find no displacement of the uterus or pathologic conditions of the pelvis, such as tumors or inflammatory swellings, which could give rise to bladder symptoms such as this woman complains of. By using a clean catheter and cleansing the external urethra the urine obtained from the bladder does not show pus. By palpation I can not discover any signs of urinary calculus. One can readily see that this is a pathologic condition existing at the meatus urinarius. The symptoms complained of by the patient, pain more or less constant and excessive smarting, discomfort after urinating, with a frequent desire to urinate, are referred to the external end of the urethra.

As a precaution I will make a cystoscopic examination with the Kelly instruments. The assistants will place the patient in exaggerated knee-chest position and hold her there. The external genitals have been thoroughly disinfected, and the external end of the urethra is likewise carefully cleaned. I measure the caliber of the urethra with the cone shaped calibrator and select a speculum which will pass into the urethra easily without undue stretching. This one is about one centimeter in diameter. I introduce the speculum, remove the obturator, and, by means of a hand mirror, reflect light into the bladder. As I with-

draw this obturator from the speculum the bladder balloons and I can easily observe the blood vessels in the interior of the bladder, and its mucous membrane as far as I can see is normal. We have a beautiful picture of the normal net-work of blood vessels. The granulation appearing tissue, seen at the external meatus, extends about an inch into the canal. The family physician thought she had chronic cystitis. It looks much like carcinoma, but carcinoma of the urethra is very rare. I will remove a small portion and have it examined by the pathologist.

It is a very easy matter to dilate the urethra of the female when it is necessary with the index finger so one can make a thorough digital examination of the interior of the bladder. It can even be done by several sittings without an anesthetic. Here I am careful to dilate only the external portion and not carry the finger into the bladder so as to run the risk of infecting that. We will keep the urethra dilated for a few days, wash out the bladder with boracic acid solution, and wait for our report from the pathologist.

Professor Skene of Brooklyn, a distinct authority on diseases of the female bladder and urethra, says of neoplasms of the urethra: "These growths have been variously known as carunculae, cellulo-vascular tumors, fleshy and vascular growths, fungoid excrescences, strawberry and raspberry tumors, each name sometimes having been used to cover the whole class." He makes a classification after Winckel's, which is as follows: Papillary condyloma, glandular cysts, myxadenoma, mucous polypi, vascular-angioma, varices, phlebectases, connective tissue fibroma, sarcoma, epithelial-epithelioma, carcinoma, compound papillary polypoid angioma, erectile tumors.

Case 4.—Age 61; German. Family history: Parents dead; one brother living; eight brothers and one sister dead; brothers died in early childhood. Personal history: Has borne eleven children; seven living; labors natural. Health good until two months ago she noticed left breast enlarged and painful. Has been able to attend to her work since then. Nothing hereditary in the family so far as known.

There is a tumor of the left breast, the diameter of which I estimate to be three by four inches. From the fact that Billroth, out of 440 tumors of the breast, found only 18 per cent. non-malignant, we are justified in looking upon a breast tumor as a grave matter. Now, when we take into consideration that sarcoma of the mammary gland is rare compared to carcinoma, and that it is more frequently met with in young women, we are inclined to look upon this as a carcinoma, if it is malignant at all, rather than sarcoma.

This tumor is irregular and movable, has begun to involve the skin, but has not involved the chest muscles or chest wall. On one portion of the surface we can trace a line of infected lymphatic glands, and there is marked contraction of the nipple. These are both characteristic signs of carcinoma, as distinguished from sarcoma. There is severe and almost continuous pain, while in sarcoma there is rarely severe pain. Upon examining the glands of the axilla I find them enlarged. One especially is large. The lymphatic glands are rarely infected in sarcoma. We can readily eliminate an inflammatory swelling as the cause of this tumor. Its nodular conditions and density eliminates a fatty tumor. Our diagnosis then is carcinoma of the breast with involvement of the axillary glands.

I consider no rule which can be more safely followed in well defined tumors of the breast than to always remove them. I proceed with the operation

by making an incision from the axillary space along the border of the pectoralis major muscle toward the sternum in such a manner as to make one side of it, near the center of the breast, include an elliptical piece of skin surrounding the nipple. The skin over the center of the breast, as far as involved, I seek to include in the tissue to remove. I now remove the mammary gland, entire, including the tumor, keeping as far away from the indurated tissue as possible until I have removed the whole mass, and then follow carefully my dissection into the axillary space, and, with extreme care, I remove all loose connective tissue, fat, and several well-marked, enlarged, lymphatic glands.

I now feel that I have done all that is possible to do with any certainty of benefiting the patient. All bleeding points were caught in artery forceps by my assistants as rapidly as exposed. I now twist or tie these points according to their importance, using cat-gut for tying. I now close the wound with interrupted silk-worm gut sutures. I place a short rubber drainage tube in the axilla so as to drain the lower angle of the extensive wound. After tying the sutures, a liberal dressing of absorbent gauze is placed over it and the tissues still further supported with adhesive straps.

The pathologist reports that the growth is carcinoma.

AN EPIDEMIC, SEPTICEMIC DISEASE AMONG FROGS DUE TO THE BACILLUS HYDROPHILUS FUSCUS.

FROM THE PATHOLOGIC LABORATORY OF RUSH MEDICAL COLLEGE,
CHICAGO.

Presented before the Chicago Pathological Society, April 11, 1898.

BY FRANK HORACE RUSSELL, A.B.

During the last half century or more science has made an extensive use of frogs in her laboratories; they have been used to demonstrate the laws and facts of biology; to ascertain the presence and effect of a variety of poisons; to show the circulation of the blood and the nature of the processes of inflammation; to contrast the action of different currents of electricity upon the muscles; to demonstrate the action of curara in destroying the properties of motor nerves. Notwithstanding the close observation to which this laboratory animal has been subjected during recent years, observers have rarely found in it evidence of disease.

In 1891 Sanarelli described and named the organism under consideration. He discovered it while performing some inoculation experiments upon frogs. They accidentally became infected and death soon resulted and this so seriously interfered with his work that he was led to investigate the cause, isolated the bacillus and described the growth of the cultures on plates, glycerin-agar, agar-agar, gelatin, serum, blood serum, and potato. The cold-blooded animals for which the micro-organism was pathogenic were frogs, toads, salamanders, lizards, sunfish and fresh-water eels. Among the warm-blooded animals which died of the infection were guinea-pigs, rabbits, new-born dogs, new-born cats, mice, field mice, chickens and pigeons. The source of the bacillus Sanarelli claims to be in water. Out of twenty-six water-supplies which he examined he found it present in two.

In 1893 the attention of Trambusti was called to this organism because of an extraordinary mortality among the frogs in the laboratory in which he was experimenting. He identified it with that described by Sanarelli. His investigations in this direction had mainly to do with the physiologic action of the toxic products of the micro-organism upon frogs. He divided his experiments into three lines: 1. The action of the pure culture. 2. The action of those substances soluble in alcohol. 3. The action of those substances insoluble in alcohol. Besides this he investigated the chemic reaction of the muscles, brain and spinal cord of the frog after the injection of the toxic products of the organism.

During the same year the organism was discovered and identified by Rogers. His attention was directed to it because of the death of frogs in the laboratory after the introduction of a fresh lot.

During October 1897 an epidemic broke out among the frogs kept for experimental purposes at the laboratory of Rush Medical College, and was so remarkable as to demand special attention. The frog tank is a zinc-lined box through which a continuous stream of hydrant water flows. In the bottom were placed some porous rocks of various sizes upon which the frogs could perch and the outlet of the tank so placed that about three inches of water continually remained in the tank. At the beginning of the school year a new supply of sixty frogs was put into the tank along with eighteen which had been kept over from the preceding year. In a short time they began to die and during six days about seventy perished, while not many days passed before the remaining ones died. The tank was then thoroughly sterilized, the sharp-cornered rocks replaced by boxes of sand, and a new lot of frogs put in. A few of these died, but by removing the affected ones as soon as any symptoms developed the remaining ones have been fairly well protected.

The symptoms following infection commenced with a disinclination to move. When touched on the end of the nose there was not the customary response. Along with this lassitude there was swelling of the abdomen, which varied some what as to degree. There was also more or less change in color. The dark greenish hue faded to a greenish-yellow tinge; especially was this marked around the black spots on the back. The change in posture was noticeable. The animal changed from a semi-erect position to a horizontal. The head was not held up but carried on the same level as the body. Rather late in the infection the legs were thrown out from the body. The fore legs had their palmar surfaces directed outward. The hind legs took a position about at right angles to the body. When urged the frog did not jump but tried to get along by a creeping movement. During this stage swimming was difficult. Shortly before death muscular contractions were observed, during which the hind legs were thrown as far forward as the head. These spasms were of short duration but recurred. Toward the end of the disease there was coma and during this stage all outward signs of life disappeared. The body showed no rigidity and remained in any position in which it was placed. When the thorax was cut open the heart was found still beating.

At least sixty frogs were examined postmortem. All of these presented practically the same lesion whether infected spontaneously or inoculated with cultures.

In making the examination the following precau-

tions were taken: To prevent contamination all instruments were sterilized with heat. As each cavity was opened inoculations were made on various media and at the same time cover-slip preparations were made. Each organ was examined in the same way. Cultures were made upon the different kinds of media but in addition to this, provision was made to grow the organism in the absence of oxygen. The tissues from all the organs and from the muscles were preserved for sectioning. The hardening fluids used were alcohol, corrosive sublimate, formalin and Mueller's fluid.

The following is a résumé of the most important findings in the examination of the dead bodies: The tongue in most cases had hemorrhagic spots upon its upper surface. The muscles, especially those of the thigh, contained more or less infiltration of blood. The appearances varied considerably; sometimes there were only a few spots which were large in size, one was observed which was nearly the size of a pea, sometimes the points of hemorrhage were very small and thickly set. In this form all the muscles of the legs and abdomen were involved and distinctly red in color. The abdomen was distended. An incision revealed a serious blood-stained fluid, found subcutaneously and in

Occasionally bacilli appeared isolated and at times short chains were seen, and sometimes a number are clumped together.

CULTURES ON DIFFERENT MEDIA.

1. *Agar-agar plates, twenty-four hours old.*—In shape the colonies are round, edges well defined, and regular with a few indentations about the periphery. Usually a dark spot appears in the center. The culture as a whole presents a granular appearance. In color it has a slight bluish tinge when viewed with the unaided eye. Under the low power of the microscope it is yellowish. On the second or third day a ring appears about midway between the central dark spot and the periphery, which encloses a darker colored area.

2. *Plates on gelatin, twenty-four hours old.*—The colonies are yellowish in color and uniformly granular, the edges well defined but a little ragged. After the second day they can not be studied to any advantage because the gelatin is liquefied.

3. *Cultures on agar-agar slants.*—The organism grows rapidly on this medium appearing first in three or four hours as a whitish gray line along the streak of the needle. The edges often show round colonies which possess a pearl-like glistening. In its growth it becomes raised above the surface of the medium and spreads slowly from side to side. In two or three days it turns to a dirty gray, gradually changing to a dark amber color which becomes more pronounced with age. This amber color is not only present in the cultures but also becomes diffused through the medium. There is a radiating appearance to the culture with a narrow zone about the edge which is light in color.

4. *Blood serum.*—Examined after twenty-four hours it shows an ash gray color. The growth is quite spreading with undulating edges. In the bottom of the tube is a quantity of fluid due to the liquefaction of the media. This is cloudy, resembling the growth in bouillon. The growth on the slant stops at the edge of the fluid. After forty-eight hours the liquefaction is increased. The growth looks milky and is partly undermined at the edges.

5. *Glucose agar* to which has been added from two to three drops of glycerin and inoculated on the slant shows a spreading diffuse growth. After about twelve hours a slight blue fluorescence appears, which again disappears in about two days.

6. *Glucose agar, stab culture, twenty-four hours old.*—On the top there is a growth about the point of puncture. Along the track of the needle and branching from each side are many gas bubbles.

7. *Bouillon, twenty-four hours old.*—The fluid is diffusely clouded. When shaken slightly it is seen to contain a grayish-white sediment which looks like rolling clouds. In the bottom there is quite a collection of the same material. A characteristic odor is present which is a combination of two odors, a slightly fetid and an aromatic odor.

8. *Glycerin agar, twenty-four hours old.*—Here a white line appears along the track of the needle. The growth does not tend to spread much. There is a slight bluish fluorescence at the edges. The growth is slow and does not turn dark, as is the case on the agar-agar. The color of the media remains unchanged.

9. *Lilmus milk, twenty-four hours old.*—Nearly the whole of the contents of the tube is coagulated.

Fig. 1.—Necrosis in spleen of a frog. Stained with hematoxylin and eosin (x 200).

all the cavities of the body. In quantity this was relatively large, especially in the abdominal cavity. The lungs were sometimes distended with air but more often collapsed. The heart muscle was pale and flabby. The stomach and intestines were markedly distended. The blood vessels on their surface were much congested. Upon opening these viscera a large amount of jelly-like material was seen. The spleen was soft and contained considerable blood, the liver dark brown in color and of a mottled appearance. It was soft in consistence. The gall bladder contained considerable greenish-yellow fluid. The kidneys were negative. In the bacteriologic examination, cultures were obtained from all the organs and cavities of the body. Cover-class preparations showed a large number of bacteria. The organism was a bacillus (Fig. 3), in shape short and thick with rounded ends. It appeared at times almost egg-shape. Its size in the cultures varied greatly according to age. When examined from the fluids of the body the characteristic appearance was in twos joined together end to end.

The color is light purple. After forty-eight hours the coagulum has become much firmer and reduced in size until fluid and coagulum are about equal in quantity. The color of the fluid now becomes cherry-red.

10. *Gelatin stab, twenty-four hours old.*—A grayish-white growth appears along the whole path of the needle. At the top there is a depression of liquefaction about the size of a pepper seed. Gas bubbles often appear along the needle track. At forty-eight hours there is liquefaction at the top, the size of a pea, with more or less liquefaction along the whole needle track. In about four days liquefaction is complete.

11. *Potato, twenty-four hours old.*—The growth when turned toward the light is glistening. At first it is straw-colored; if any portion of the potato is somewhat dry, the growth here is orange yellow. It does not show much tendency to spread. The outer edge is irregular. Many raised points can be seen resembling blebs. Examined forty-eight hours after inoculation it has a dirty appearance. The blebs become more prominent. On the fourth day the growth begins to take on a chocolate color which resembles the growth of the bacillus of glanders.¹ The brown color becomes more marked with age.

Cultures do not die readily. They will live at least five months upon media without being transplanted.

LETHAL TEMPERATURE.

The bacteria are killed by a temperature of 50 degrees C. in from five to eight minutes. The method employed to determine the point of thermal death was as follows: A bouillon culture was put into small sealed glass tubes. These were put into water maintained at a temperature of 50 degrees C. At different intervals these were removed, broken open and inoculations made into media. Five minutes at this temperature greatly retarded the growth and eight minutes was sufficient to kill them. Cold will not kill them. After being exposed for seventeen hours at a temperature of -20 degrees C. they still grew when put into the incubator, though their growth was greatly impeded.

MOTILITY.

The organism examined by means of the hanging drop exhibits active motility. It has the power of both backward and forward motion. If its movements are watched, frequently it will be observed to start in a certain direction, stop suddenly, and without turning to go in exactly the opposite direction.

REACTION TO STAINS.

It does not stain by Gram's method, but takes the other common stains readily. Methylene blue makes a very distinct and convenient stain. For blood preparations a simple and easy process of staining is by the use of eosin and methylene blue. The red blood cell is stained light green, the nuclei of the red and the white blood corpuscles together with the bacteria are stained blue.

Another method used for studying the action of the bacteria in the blood is the following. A staining solution is made by adding methylene blue to a physiologic salt solution to the point of losing its translucency. A wall of vaselin is made on the slide

inclosing an area somewhat smaller than the cover-glass and into this a little fresh blood is put with two or three drops of the staining solution. The cover-glass is put on and the preparation examined under the immersion lens. The blue readily stains the bacteria, the leucocytes and the nuclei of the red blood corpuscles. The bacteria can be seen moving in the midst of the corpuscles. Some are isolated and move rapidly; others show chain formation and are sluggish. Occasionally a leucocyte is broken down and is seen to contain bacteria.

FLAGELLA.

Flagella (Fig. 4) were demonstrated by the use of a modification of Loeffler's method of staining. Cultures on agar four or five hours old gave the best results. The older bacilli do not show any flagella. A platinum wire was flattened out for the purpose of touching the culture without getting any of the media. This wire was then introduced into a small quantity of distilled water when a string of bacteria could be observed leaving the needle. A very fine capillary tube was then filled with this water containing bacteria and very fine drops placed on a slide pre-

Fig. 2.—Intermuscular hemorrhage in the thigh of a frog (x 200).

viously cleansed with alcohol and acid and then heated to a redness. When dry the slide was fixed in the flame in the ordinary way. The mordant was applied and the slide held high above the flame (no alkaline or acid solutions were used). After steaming the slide was washed with distilled water and then alcohol. Carbol-fuchsin was then added and heated to the point of steaming. The slide was then washed, dried and mounted. By this method it was ascertained that the organism has but one flagellum. This is attached to one end. It appears wavy and is from four to six times the length of a bacillus.

INOCULATION EXPERIMENTS.

1. Frogs were inoculated in the thigh, in the peritoneum and in the lymph sac on the back. They gave no symptoms additional to those already given in describing the epidemic disease, except occasionally after inoculation a frog would have a puerile coughing during which a frothy fluid would come from his mouth. After these inoculations with virulent cultures death ensued in from eight to sixteen hours.

¹ This is easily differentiated from glanders by the use of a saturated solution of mercuric chloride. A few drops added to the culture turns the bacillus of glanders to a bluish-green color which persists several days. A few drops of the solution added to the bacillus hydrophilus fuscus turns it to a milky-white color. In the latter the original color returns after a short time.

2. The rabbit was inoculated into the ear vein; this produced death in a little over two days. The inoculated ear was enormously swollen and drooped to the floor. Upon examination no exudate was found subcutaneously; a slight amount of blood-stained fluid was in the abdominal cavity, also in the pleural cavity. The heart contained much darkly colored blood; the liver, spleen and kidneys were congested; the stomach and intestines were distended with gas; the bladder was full of urine; the lungs were normal. Muscular hemorrhages were not noticeable. One of the rabbits that was used had been made immune to pus microbes. It was inoculated in the abdominal cavity, also in the vein of the ear. Each time it became sick but resisted the infection.

3. The guinea pig was inoculated in the abdominal cavity. In about an hour it had a severe chill; in another hour it became restless, breathed rapidly and showed evidences of fever; in three or four hours after inoculation it became very weak and continued in a state of prostration until death, which occurred eight hours after inoculation. The internal lesions were practically the same as in the rabbit.

Fig. 3.—Bacilli in blood of frog. Stained with methylene blue (x 1200).

4. The house mouse was inoculated in the abdominal cavity with a culture from agar-agar shaken up with a little bouillon. Soon after inoculation the mouse became very restless, ran about the cage and scratched itself. Later it shivered and soon went into a prostrate condition and died two hours after inoculation.

5. The white rat died five hours after inoculation. The symptoms were shivering, bristling of the hairs, and later prostration.

6. Two different pigeons were tried. They were inoculated in the breast and the axillary veins. They became sick after each inoculation but resisted death.

EXAMINATION OF THE TISSUES MICROSCOPICALLY.

1. Frog.—The tissues were stained with hematoxylin and eosin and with methylene blue. The spleen shows evidences of marked congestion. Through the organs there are areas of retrograde changes and areas of congestion: *a*. The areas of retrograde changes differ much in size and shape and are always irregular. The groundwork consists of a granular eosin-staining material not uniform in thickness. Around the heavier staining material are spaces of less den-

sity. This groundwork is thickly studded with hematoxylin staining material, especially where the groundwork is less dense. This hematoxylin staining material, including nuclei and their fragments, exhibits a great variety of forms and staining properties. There are lightly staining nuclei more or less enlarged. The outline stains dark and the center light. Within the nucleus the chromatin is collected in granules which have a tendency to collect in bunches around the periphery. Although these nuclei in places are regular and round in outline, they are mostly irregular and abnormally shaped. They assume a large variety of shapes, pear shape, dumb-bell shape, crescent shape, K shape, spiral shape. Some are ragged in appearance where one side of the nucleus has disappeared. Another variety of nuclear substance is bodies which stain very deeply with hematoxylin, homogeneous in character, resembling a fused mass. In size they vary from those just visible to the size of a red blood corpuscle. They are globular in shape. Resembling these globular bodies are oblong bodies, but which do not show the differ-

Fig. 4.—Flagella (x 1200).

ence in size. They have a tendency to mass and sometimes are arranged slightly star shape. Another variety is irregularly shaped dark granules. These do not stain evenly, are accumulations of granules of chromatin, very ragged in outline and joined together in many ways, not infrequently cauliflower in shape. In these areas of nuclear fragmentation a few isolated red corpuscles appear. Some fields contain more than others, but they are comparatively few. Many of the corpuscles are distorted in shape (Fig 1). Sections stained with methylene blue show that these fields contain many bacilli, frequently distributed in clumps. Stained with Weigert's fibrin stain, minute bands of fibrin run in all directions inclosing the nuclear granules in a delicate network. In the necrotic areas there are many hematin crystals, appearing as isolated single crystals and also collected in masses. *b*. The congested areas.—The congestion in these areas is intense. So compact are the blood corpuscles that no spleen structure can be seen except at the edges of the areas. Here the blood fills the lymph spaces and infiltrates the tissues.

The muscles present changes of interest. Those of

the thigh were examined. In looking at a cross section a number of areas are observed showing retrograde changes in the muscular fibers. These are always accompanied with hemorrhage. The changes in the fibers are of two varieties: *a*. Through compression.—In the densely congested areas the muscular fibers undergo pressure atrophy. Some have become so small that only a delicate band is left. These may show further retrograde changes or may not. *b*. Degeneration.—The changes seen are the separation of the fasciculi from one another, accompanied by a wavy appearance. The crossed striæ disappear. The fibers refuse the eosin stain and are dark yellow in color. Subsequently the nucleus disappears and there remains only a mass of granular débris. Fibers are then seen in all stages of degeneration. An individual fiber may be observed in which a part may be undergoing a retrograde change and the remainder be little affected (Fig. 2).

The lungs and kidneys show little or no change.

In the liver marked changes occur. The retrograde process is of a diffuse character in which the whole liver participates. In comparing this with the normal liver one of the first things to be noticed is the differ-

Fig. 5.—Focal necrosis in the liver of a guinea pig (x 200).

ence in staining property manifested by the cells. In the place of the protoplasm taking the eosin stain exclusively, as in the normal liver, it takes the mixed stain. The cell bodies do not stain evenly. The protoplasm has the appearance of a bunching of granular material so that some parts of the cells are denser than others. This often affects the contour of the cell; the edges are often irregular and ragged; sometimes no distinct cell outline can be seen at all; sometimes the outline of the cell stains rather deeply while the center shows little remaining cell matter and the nucleus, if it has one, appears free. In the protoplasm of the cell are many darkly stained granules. In a single cell there are from one to eight or ten. These differ in size from those barely visible to those one-tenth the size of a normal nucleus. They do not occupy any special place in the cell. The nuclei of the cells show all stages of degeneration. They have suffered far less, however, than the cell bodies. Some of the nuclei appear bladder-like and contain little chromatin, others show a mass-like accumulation of chromatin granules about the edges, often located almost exclusively on one side. The nucleus fre-

quently loses its round contour and becomes elongated, assuming many shapes. In some of the cells the nuclear membrane has disappeared leaving an irregular mass of chromatin granules. The capillaries are dilated and contain considerable blood, together with cell detritus and fragmented nuclei. The walls of the capillaries are broken in many places and the blood corpuscles have escaped among the cells. Bacteria are found in abundance in the capillaries, appearing usually in bunches and often occupying many of the broken down cells.

Cross sections of the spinal cord and brain show that these organs do not escape the destructive action of these agents. Quite extensive necroses occur in both places. When sections are stained with methylene blue bacteria appear in abundance in these tissues. The minute study of the lesions and effects of the toxins on the nervous system will be deferred to a subsequent time.

In frogs, where infection has lasted several days the lymph sac on the back shows great changes (it is here that inoculations were made). In the recent state the sac is quite well filled with jelly-like material. In character it is a rather soft, semi-transparent mass which can easily be squeezed between the thumb and finger.

Microscopic sections show that these growths are attached to the inner surface of the skin. They appear pedunculated. A cross section of one of these masses shows a dark center and a light periphery. Blood vessels are present. The vessel walls are thin and lined with flat endothelial cells. With high power the dark center is seen to be made up of a large aggregation of nuclei and nuclear fragments, mostly the latter. There are dark granules which are round, oblong and irregular, together with a great number of very fine granules. Mixed up in this mass of broken down nuclei are a few red blood corpuscles, many leucocytes and a few lightly staining nuclei distorted into many shapes.

The periphery shows a somewhat reticulated structure which to some extent enters into the formation of the dark center described. In this eosin staining groundwork are a few blood cells with a few nuclei and granules.

Fibrin is present in these structures, as is shown by Weigert's fibrin stain.

2. Guinea pig. The tissues of the guinea pig show evidences of an infection, although the time between the inoculation and death was only eight hours. The spleen and the liver contain most of the changes. The muscles, testicles, lungs and heart do not present any marked pathologic conditions. *a*. In the spleen a strong contrast exists between the Malpighian corpuscles and the spleen pulp on account of the large amount of blood in the latter. In looking over the specimen with the low power many dark spots appear scattered through the pulp. These areas are relatively small, contain a granular center and are full of bacteria. Surrounding this there is quite an extensive zone consisting of leucocytes more or less broken down, and nuclear fragments. The pulp is everywhere greatly congested with blood. The Malpighian corpuscles show no changes. *b*. The liver also shows many focal necroses. These do not choose any special part of the lobule by preference. They are mostly small in size, some so minute as to occupy only one liver cell. The central part is finely granular and stains darker than the liver cells. In the process of

disintegration the cell body seems to show the first change, which is a granular appearance. The outline becomes irregular and ragged. The chromatin of the nucleus, which soon shows changes, collects at the periphery in masses. Frequently it is nearly all on one side. The circle becomes broken and the nucleus as such disappears. The cells through the liver have a more or less granular appearance. The edges are not easily made out and their nuclei do not stain evenly. The capillaries are dilated and contain many cell fragments and granular material.

3. Rat. *a*. Liver.—In looking over the specimen one of the first things to attract attention is the large number of leucocytes which it contains. These are often gathered in masses. The liver cells contiguous to this round cell infiltration may or may not be affected. In not a few places the liver cells have undergone disintegration. Away from these areas the liver cells do not show any particular change except

cles show no change. *c*. The lungs show no changes except a moderate congestion.

4. Rabbit. *a*. The spleen shows much congestion. In the pulp a large amount of hematoidin crystals exist, isolated and in masses. The Malpighian corpuscles show little change and are not infiltrated to any extent. There are no focal necroses. *b*. Many of the liver cells appear rather narrow, surrounded by distended capillaries filled with blood. They are granular in appearance. In places much of the cell body has left the nucleus, leaving it almost and sometimes quite free. Some of the nuclei have assumed abnormal shapes. The capillaries contain protoplasmic and nuclear material mixed in with the blood. Liver cell nuclei, having more or less surrounding protoplasm, can be seen distinctly in the lumina of the capillaries. In many of the large veins and in many of the central veins of the lobules can be seen free bodies consisting of eosin staining material in which are mixed darkly staining granules. There are no areas of round cell infiltration. Throughout the specimen are scattered a large number of hematoidin crystals. *c*. In the kidney the convoluted tubules show granular changes and stain irregularly. The lumen contains granular material, epithelial cells and nuclear fragments. There are no focal necroses and very little congestion. *d*. The muscles and stomach show no changes. *e*. In the brain the most noticeable thing is the congestion of the blood vessels.

5. Mouse. *a*. The liver shows focal necroses which answer in description to those found in the liver of the guinea pig. The liver cells are granular. Many of the nuclei have lost their shape and show different forms. In the capillaries there are cell fragments consisting of cell protoplasm and nuclear granules. Small masses are present in the large vessel as was described in the liver of the rabbit. When stained with methylene blue bacteria appear in large number in the capillaries. *b*. The testicles, epididymis and heart muscle are negative. *c*. The kidney is very similar to that described in the rabbit.

A fact to be noted in the examination of the tissues is the relation of the virulency of the organism to the focal necroses. As a culture grows old it becomes less virulent. Virulency is best retained in blood taken from the heart and kept in sealed tubes. When a culture which is two months old or more is injected into the frog, sickness is produced which rarely results in death. Thus different grades of virulency can be observed. If after an inoculation with a culture attenuated by age a frog survives two days or more, no focal necrosis may be expected. The congestion in the organs remains about the same, except less marked. The exudation into the serous cavities is also less noticeable. This same relation between the degree of virulency and the amount of lesion holds true with the warm-blooded animals. The greater the virulency the greater the amount of necroses.

As to the mode of infection nothing definite can be stated. If bacteria are put into water and into this is introduced a frog having a cutaneous lesion, infection will take place. Several times frogs which supposedly had no cutaneous erosions were put into infected water and only one died. In this case it would be impossible to prove that no lesion of the skin existed. Bouillon cultures of the organism on several different occasions were introduced into the stomach by means of a glass tube, but with no apparent effect. It seems very probable, therefore, that the sharp-cornered rocks.

Fig. 6.—20, tracing with the cardiograph of the frog's normal heart beat. 21, five minutes after injection of toxins insoluble in alcohol. 22, fifteen minutes after injection of toxins insoluble in alcohol. 24, thirty minutes after injection of toxins insoluble in alcohol. 15, contraction of normal gastrocnemius muscles. 18, gastrocnemius muscle one half hour after injection of toxins insoluble in alcohol. 11, tracing of normal heart. 12, ten minutes after injection of toxins soluble in alcohol. 14, thirty minutes after injection of toxins soluble in alcohol. 17, gastrocnemius muscle thirty minutes after injection of toxins soluble in alcohol.

the granular appearance of its protoplasm. *b*. Spleen.—The most noticeable feature is the congestion. The Malpighian corpuscles appear very prominent. The lymph spaces are greatly crowded with blood. In a few of the Malpighian corpuscles some infiltration has taken place. In a few areas there is cell fragmentation about the edges of the Malpighian corpuscles. In them we see lymph cells which stain lighter than usual. They have lost their normal shape and many appear vacuolated. Nuclear fragments and bacteria are found in large numbers in these areas. *c*. Kidney.—No marked changes are to be seen except in the veins and convoluted tubules. In some of the large veins there can be seen breaks in the walls. Here the blood infiltrates the tissues, accompanied with a dissolution of the contiguous tubules. At the junction of the vein with the tissues there are fragmented nuclei. Some of the nuclei of the vein can be seen free, still retaining their natural shape. The lumina of some of the convoluted tubules are very irregular and ragged. *d*. The muscles, stomach and heart mus-

in the frog tank had much to do with the original epidemic. The frogs gliding over these sharp projections could easily sustain injury of sufficient extent to admit of the entrance of the bacteria.

The source of the bacillus is yet an open question. During the epidemic, bacteria were found in great numbers in the water of the frog tank. It has been ascertained also that a frog inoculated with the bacillus will infect the water. It is evident, therefore, that there might be two ways to explain the source of the organism. The bacteria might be in the Chicago water or they might come with the frogs. The tap water has been examined several times with negative results. A frog, in which was kept an open wound, was put into running water and retained there for two weeks. No infection took place. It is most probable, therefore, that the bacteria came with the frogs.

Widal's test was performed on two different occasions. Frogs were used which were at the point of death. The serum was diluted thirty times and no agglutination took place. With five to ten dilutions there was agglutination, which after a few hours in a warm place disappeared. At another time forty dilutions were made with no clumping of the bacteria.

TOXINS.

In order to test the toxins a culture of bouillon was placed in the incubator at a temperature of 37 degrees C. and left to grow for three weeks. This was then filtered through a Chamberlain's filter. When 2 c.c. of this filtered fluid was injected into the lymph sac of the frog no effect whatever was produced.

Dead bacteria were also injected into a frog. This produced some indisposition which was shortly recovered from.

This filtered bouillon culture (following Trambusti's method) was subjected to farther processes in order to get the toxins in a more concentrated form. To about 115 c.c. of this fluid 290 c.c. of absolute alcohol were added. With occasional shaking the alcohol was left in contact about two days. Then this mixture was filtered through two thicknesses of filter-paper. The filter-paper was then dried and washed with 22 c.c. of distilled water. This constitutes the toxins which are insoluble in alcohol. The fluid which passed through the filter was evaporated in a water bath. Then 30 c.c. of absolute alcohol were added to the residue so as to precipitate all the toxins which were not soluble in absolute alcohol. This was filtered and the filtrate evaporated a second time. This last residue was then dissolved in 15 c.c. of distilled water. Thus two classes of toxins were obtained, those which are insoluble in alcohol and those which are soluble. When these toxins are injected into frogs marked effects are produced.

1. *Toxins which are insoluble in alcohol.*—A frog was prepared in the usual manner and a tracing of its normal heart taken by the cardiograph (Fig. 6). Then 1 c.c. of the solution of the toxin was injected into the lymph sac of the thigh and also into the peritoneal cavity. Five minutes after injection a tracing was taken (Fig. 6). The horizontal distance through which the lever moved was twice that of the normal. Diastole was prolonged. The tracings also show a retarded action. The following table shows the number of beats per minute taken at different times subsequent to the injection:

Time.	No. beats.
11:17	35

11:25	31
11:46	28
1:01	22
1:07	17
1:12 heart stopped in diastole 4 or 5 minutes.	
1:27	5

About two hours after injection the action of the heart became peculiar. It would stop in diastole for four or five minutes. Then it would begin to beat again. The rate was slow, being only five to eight times per minute. After six to thirteen beats it would again stop in the same way. Although the rate was very slow, every beat was forceful. The ventricle contracted so firmly as to become white.

Tracings made by means of the myograph on the gastrocnemius muscle showed changes which can best be seen by comparing Figs. 15 and 18. A short curve appears immediately after the long curve; then a straight line follows until the next long curve.

2. *Toxins soluble in alcohol.*—The frog was prepared and treated in the same way as already described (Fig. 11). Ten minutes after injection there was no variation in the curve except it was stronger (Fig. 12). The rapidity of the heart was the same. Thirty minutes after injection the action of the heart was so feeble that practically a straight line was obtained by the cardiograph (Fig. 14). Thirty minutes after injection the gastrocnemius muscle showed a decided variation from normal (Fig. 17). The down stroke of the major curve is continued below the basement line, then arises a little above it and falls again to the basement line. Half way between the major curves is a short curve. Thus we have two toxins produced by this organism, each having a powerful effect upon both the voluntary and involuntary muscle. (A more extended study of the toxins in connection with the nervous system is reserved for a later date.)

It is quite evident that the cause of our epidemic in the frog pond is identical with that described by Sanarelli, Trambusti and Rogers. Our experiments have very similar conclusions to theirs, but a few things have been added. In looking over the literature there is no record of necroses observed in the organs, the flagella had not been studied, the thermal death-point had not been ascertained, and no observations had been noted in relation to the degrees of virulence. Two differences are to be noted between Sanarelli's organism and ours: we fail to get gas bubbles in the substance of the media after inoculating a slant of glycerin-agar, unless the needle penetrated it. Another difference is in the inoculation experiments with the pigeon. Here infection by an intravenous injection produced sickness from which the pigeon recovered on the second day; in his case it died.

To sum up, we have been studying a water organism, a short thick bacillus with rounded ends, which possesses active motility and has but one flagellum, is chromogenic, gas-producing and aerobic, but grows also to some degree without oxygen. It grows well upon all culture-media. Gelatin is liquefied, bouillon diffusely clouded, upon agar-agar there is produced in a few days an amber color which also colors the media, potato produces a chocolate-colored growth, litmus-milk is made acid, glycerin agar produces an ash-white growth but does not change in color and glucose-agar shows gas formation. It grows best at body temperature and does not stain by Gram's method. The cold-blooded animals for which it is

pathogenic are frogs, toads, salamanders, lizards, sun-fish, and fresh-water eels. The warm blooded animals which succumb to infection are guinea pigs, rabbits, new-born dogs, new-born cats, common mice, field mice, bats, chickens and pigeons (Sanarelli). The virulence of the organism varies greatly. Cultures gradually lose their virulence with age, but blood taken from the animal and sealed in tubes will retain it for months. Infection produces a septicemia. Warm-blooded animals are seized with shivering and restlessness, followed by prostration and death. Cultures can be obtained from the blood and from all the fluids and organs of the body. Exudations of blood-stained fluid occur in all the serous cavities, especially marked in the peritoneum. Histologic examinations reveal focal necroses in the spleen, liver, brain and spinal cord with congestion in the other organs. In the frog, intermuscular hemorrhages occur with destruction of muscular fibers. The organism produces powerful toxins which were divided into two classes, one resembles in its action digitalis and the other veratrin.

CHRONIC NASAL CATARRH.

Read before the Sixty-sixth Semi-annual Meeting of the Fox River Valley Medical Association, Elgin, Ill., May 24, 1898.

BY HENRY G. OHLS, M.D.

CHICAGO.

What is nasal catarrh? I believe the only comprehensive definition is: A pathologic change in the system or in the structure of the nares, accompanied by altered function of the mucous membrane. Nor do I place the constitutional before the local causes on account of their greater importance and frequency. On the contrary, the large majority of cases depend upon local causes and are amenable to local treatment. My definition includes a great variety of conditions, and for the very good reason that catarrh, so-called, necessarily includes a great variety of conditions or diseases requiring the most diverse measures, medicinal and operative, for their successful treatment.

It is a popular fallacy that catarrh runs into, or predisposes to, tubercular diseases. On the contrary, Bosworth ("Diseases of the Nose and Throat," Vol. 1, page 99) ridicules the idea of a catarrhal diathesis, and claims that catarrhal inflammation always remains catarrhal, producing hypertrophy, never ulceration or necrosis. As to catarrh inducing tuberculosis, Dr Ingals (*JOUR. AMERICAN MEDICAL ASSOCIATION*, June 12, 1897) from a careful analysis of 14,953 private case-records, finds that nasal catarrh is less frequent in a given number of tuberculous patients, than in the same number of healthy people.

Physiology.—Formerly the nose was considered the organ of smell, but physiologic research has demonstrated that the olfactory function, although exclusive, is no more important than its functions in respiration, in phonation and in audition. Indeed, the impairment or loss of the sense of smell is a far less serious matter than interference with the other functions.

The respiratory function includes filtering, warming

and moistening the inspired air, all of which take place in the ciliated portion or middle and lower meatus. Coarser particles inhaled are entangled in the vibrissæ and, unless the air inhaled is excessively dust-laden, the finer particles are arrested by the cilia and carried downward by the serum. The air is warmed in its passage through the nares by the large mucous surface exposed and especially by the superficial location of the sinuses of the turbinates which respond instantly when the inspired air is cold and dry. Goodale (*Boston Med. and Surg. Jour.*, Nov. 5 and 12, 1896) found that the relative humidity of the air after passing the nasal chambers is near the saturation point with reference to its own temperature. Aschenbrandt and Kayser demonstrated that the turbinates secrete 500 grams of serum in twenty-four hours. Wright and Park (*Laryngoscope*, June, 1897) found that nasal mucus is not bactericidal, but is not a good medium, while many germs are washed away by it. The importance of normal functional activity on the preparation of the air for the delicate structures it encounters below can scarcely be overestimated.

The ideal nares are symmetric cavities with no opposing surfaces in contact, as Pynchon tersely describes it (*JOUR. OF AMER. MED. ASSO'N*, Dec. 12, 1897). He emphasizes impaired ventilation and drainage as the common cause of catarrh. As a *rara avis in gurgite vasto* the ideal naris is comparable to an ideally beautiful face, which does not imply that most of us need nasal operations any more than we need plastic operations for cosmetic effect. The test for operative interference is largely the amount and character of obstruction met with, whether it consists in deviation or thickening of the septum; of enlarged and malformed turbinates; of thickened mucous membrane and swell-bodies or of abnormal growths.

Chronic catarrh, for convenience of description, is divided by Ingals ("Diseases of Chest, Throat and Nasal Cavities," 3d Ed., p. 25) into four varieties. 1, Simple chronic catarrh. 2, Intumescent rhinitis with frequent swelling of the membrane on the turbinates, and on the upper part of the septum on one or both sides, but more often alternating from one side to the other. Seiss (Burnett, 1, p. 633) calls this the vasoparetic period or stage of dilatation of the venous sinuses. 3, Hypertrophic rhinitis or the state of fibrous metamorphosis of Seiss. 4, Atrophic rhinitis, usually a sequel of the hypertrophic form, but much less common.

SIMPLE CHRONIC RHINITIS

Is a catarrhal inflammation with little swelling, but great irritability of the membranes, with congestion and profuse, watery, or irritating mucopurulent secretion. It occurs among all classes and in every climate, but children are more susceptible than adults.

Etiology.—The causes of simple chronic rhinitis are not materially different from those of acute colds. The chronic form generally supervenes in subjects who, from exposure or debility, acquire frequent colds, and throughout its course the patient is liable to have frequent acute exacerbations.

Symptoms.—A history of almost constant nasal irritation, with frequent sneezing, itching and burning, and extending over many months regardless of the seasons, points toward chronic rhinitis. Headache and pain in the eyes are common symptoms. The early watery discharge later becomes thick and mucopurulent. The digestive functions are sometimes

impaired, but the general health is not often affected. Upon inspection the membrane is seen to be congested and bathed in excessive secretion. In about half the cases deviations or spurs of the septum encroach more or less upon the cavities. The membrane of the nasopharynx is generally congested and the excessive secretion forms thick gelatinous masses that are expelled by hawking. The nares may remain free, except for secretions, but the disease generally results, after months or years, in either atrophy or hypertrophy of the membrane and underlying structures.

Diagnosis.—Hay fever resembles this condition somewhat in the watery discharge and spots on the membrane very sensitive to the probe; but the former is readily distinguished by its sudden appearance and periodicity at certain seasons, by excessive swelling of the mucous membrane and the more severe constitutional disturbance as well as by the well-known results of change of climate.

Treatment.—In the treatment of simple chronic rhinitis the objects to be attained are the relief of excessive sensibility and the checking of excessive secretion. For the former, oily antiseptic sprays, such as liquid albolene, 1 ounce, with terebene, v to x, may be sprayed into the nares freely two or three times a day with Davidson's No. 50 atomizer. This also tends to check the secretion, but if greater astringent effect is desired a few grains of the following powder should be blown into the nares once or twice a day: Alum. 1, soda bicarb. 1, soda bibor. 1, mag. carb. 2, cocain mur. 2.5, iodol 20, sacch. lact. ad 100. In every case applications should be so mild as to cause only temporary discomfort followed by a sense of relief. When spots of tenderness are found, with frequent sneezing, superficial cauterization will overcome the sensitiveness without destroying the membrane. Small areas only, not over 5 to 10 millimeters in diameter, should be cauterized at one time, and about a week should intervene between cauterizations, with the use of sedative applications in the intervals.

When the secretions are thick and difficult to dislodge, antiseptic, alkaline washes give great relief, and should precede the use of the oily spray, especially in the morning when the greatest collection of secretions is liable to occur. The ideal solution is agreeably aromatic, mildly alkaline and antiseptic and of a specific gravity near that of the nasal serum (1015). These conditions are met very closely by the solution of Rhodes' tablets of the following formula, when dissolved in four ounces of tepid water. (*Jour. of Laryngol., Rhinol. and Otol.*, January 1897).

R. Potass. chlor.	2½ grs
Soda bicarb.	10 grs
Soda chlorid. C. P.	10 grs
Soda salicylate	5 grs
Soda bicarb.	5 grs
Thymol	18 gr.
Eucalyptol	¼ min.

The Birmingham douche is a convenient instrument for introducing the solution.

INTUMESCENT RHINITIS

Is the most common form of chronic catarrh, and is characterized by intermittent swelling of the mucous membranes with corresponding stopping up of the nares. Upon lying down the lower naris is generally occluded.

Etiology.—The causes of this condition are the same as those of simple chronic rhinitis.

Symptoms.—To the symptoms of simple chronic rhinitis are now added the obstruction to nasal breathing, and all the long train that logically follows. The secretions may remain thin, but are more often thickened and may form crusts difficult to dislodge, but becoming offensive if long retained. Drinking warm fluids in this condition often dislodges masses of secretion that nauseate the patient. Mouth-breathing becomes more pronounced as the amount of swelling increases and in proportion to the respiratory need. Thus with moderate swelling a patient may be unconscious of month-breathing unless extra exertion calls for more air than the nares can admit. But even when at rest a series of ordinary inspirations will be followed by a yawn or a deep inspiration. During sleep the mouth is often kept open and the patient rises with a dry throat and coated tongue. The membrane is often irritable, with spots sensitive to pressure with the probe. The slightest touch over these sensitive spots causes an intense burning sensation and is often followed by sneezing (S. F. Snow, *Med. News*, July 10, 1897). Frontal headache is a common symptom, especially when the middle turbinate is swollen. The sense of smell is abolished when the naris is occluded.

Suffusion of the eyes, with mild conjunctivitis, occasionally occurs with this condition of the nares. Inhaling through partially obstructed naris causes a partial vacuum in the passages behind the seat of obstruction. This is the principal physical factor in the chronic congestions of the membrane lining the nasopharynx, the pharynx, larynx and trachea, all of which frequently follow prolonged obstruction.

The proper ventilation of the middle ear is affected unfavorably by nasal obstruction and long-continued tinnitus is often followed by sclerotic changes that impair the hearing.

The voice is affected both by the congestion of the larynx and by the lack of resonance due to nasal obstruction. It is thus not only unpleasant as to quality, but speaking and singing become an effort that can not be long sustained.

I will not attempt to enumerate the remote symptoms except chronic cough due to some of the above conditions, and asthma which is associated with a certain proportion of cases of intumescent rhinitis. Wm. L. Ballenger (*Medicine*, November, 1897), and Titeff ("Thèse de Genève," 1896), note the aprosexia exhibited by severe cases, and attribute it to autointoxication due to accumulation of carbon dioxid in the blood. It seldom approaches in severity the same symptom in children with adenoids.

Upon inspection the nasal membrane is found swollen smoothly upon one or both sides so that the normal space is closed anywhere from a small fraction to totality. The swelling on the septum is generally far less than that on the turbinates. The membrane is usually congested. Firm pressure by the probe will flatten the membrane against the bone, but the groove thus formed quickly fills up when the pressure is removed. A solution or powder containing 4 per cent. of cocain will also quickly reduce the swelling.

Diagnosis.—The swelling of the membrane distinguishes this from simple chronic rhinitis; occurrence regardless of seasons, from hay fever; intermittent smooth swelling, from hypertrophic rhinitis. Mucous polypi are differentiated by passing the probe to either side of them, by their being movable and by the effect of cocain.

Prognosis.—Spontaneous recovery occurs rarely.

More often the disease lasts for years and eventuates in the hypertrophic form. Pharyngitis, laryngitis and throat-deafness, are common sequelæ, and are especially intractable unless the nasal cause is recognized and relieved. The aprosexia mentioned above is associated with a lessened resistance of the system to morbid influences.

Treatment.—Prophylaxis demands avoidance of exposure to the common causes of taking cold. Persons who are particularly susceptible should constantly wear woolen underclothing of suitable texture. Cold bathing or sponging with friction to cause reaction is a valuable measure. The digestive and eliminative systems should receive due attention to maintain a high standard of functional activity. Acute colds should have immediate attention. Cases of intumescent rhinitis that are mild in this variable lake climate with its sudden changes of temperature and excessive humidity improve rapidly upon removal to warm, dry regions. Mild oily sprays and alkaline washes should be used in mild cases such as in simple rhinitis. I prefer solutions of camphor, gr. $\frac{1}{2}$ to 1, or menthol gr. 1 to 3, to the ounce of albolene. When the swelling becomes annoying only on taking cold and at long intervals, the patient may be provided with a powder containing 4 per cent. cocain only to be used very sparingly at the time of greatest discomfort, which is usually in the morning or evening. It must never be used except under the strictest limitations, and the patient should never have a prescription for it. If all patients were ignorant of the properties of cocain it would be easier to confine its use within proper bounds.

Well developed cases obtain only temporary relief from the applications mentioned. When the swelling causes more frequent and annoying obstruction, removal of the excessive tissues by surgical means including cauterization offers the only prospect of speedy relief.

Cauterization of the membrane in lines (Ingals) or in spots (Bosworth) by application of chromic acid was formerly the best available means. This application, however, is painful and causes a sore that heals slowly, while the scab is hard and irritating to the tissues adjacent.

Electricity in the form of the galvanocautery offers a method that is certain, easily controlled and in every way desirable. The method perfected by Dr. Ingals (p. 538) I have used in a large number of cases with great satisfaction. After anesthetizing the swollen lower turbinate thoroughly with a 4 per cent. solution of cocain, the cold electrode is inserted and applied against the posterior end. The contact button is pressed and the electrode drawn slowly forward through the most prominent swelling. Pressure should be exerted until the operator feels the electrode "grate" on the bone. The electrode must be removed from the tissues before breaking the circuit, to avoid tearing off the eschar, and it is then allowed to cool before it is withdrawn from the nostril. The naris is sprayed with albolene containing a few drops of oil of cloves to the ounce, and iodol is insufflated. The patient is directed to wear absorbant cotton in the nostril when out of doors. He is also provided with an oily antiseptic spray to be used freely, and a powder containing 4 per cent. cocain to be used sparingly, and only when the naris is closed by swelling. On the fourth day the scar tissue is gently removed. This usually prevents the formation of adhesions. The cauteriza-

tion is repeated at intervals of two or three weeks until both nares remain freely open. Two cauterizations on each side are usually sufficient. There is no danger of destroying too much tissue if this rule is observed. In a few cases where too severe reaction follows cauterizing the whole length of the turbinate, it is better to cauterize only half a line at one sitting. The electrode is made of No. 21 platinum wire, which retains the heat sufficiently to burn through any thickness of tissue liable to be encountered in the nares. Many electrodes in the market are so light as to be mere "spiel-zeuge" as our German friends say. For some years I have used two chlorid accumulator cells of type D, three plates, to heat the electrode.

HYPERTROPHIC RHINITIS.

Hypertrophic rhinitis consists essentially in chronic thickening of the turbinates, and is often associated with malformation of these structures and with deviations and spurs of the septum. Thus the nares are obstructed and the passages irregular, causing the greatest interference with nasal functions.

Etiology.—The hypertrophic is commonly the sequel of intumescent rhinitis, and the causes are the same.

Symptoms.—The subjective symptoms are the same except that the obstruction is more constant, the post-nasal secretion more annoying and the pressure and obstruction symptoms more marked. Upon inspection the membrane is found thickened, but less congested than in the intumescent form. It is also often uneven and the swelling is irregularly distributed. The lower turbinate is most often affected, but the middle turbinate is occasionally greatly hypertrophied and presses upon the septum. Mucous or mucopurulent secretions collect in the fosse, and dry crusts form in the concavities of the septum. The posterior ends of the lower turbinates may fill the choana and project into the nasopharynx.

Diagnosis.—Pressure with the probe detects greater density than in the intumescent form, nor is the swelling reduced markedly by the application of cocain.

Prognosis.—This disease is liable to remain for many years, but a small number of cases undergo atrophic degeneration from causes at present not well understood.

Treatment.—The indications are to restore the normal contour of the nares, and the efficient means to that end are necessarily surgical. The use of acids is no more desirable or efficient in this than in the intumescent form. Of surgical instruments the scissors, saw, snare, trephine, spoke-shave and electrode each has its advocates, and each has its peculiar field of usefulness.

Soft hypertrophies hanging downward like a curtain from the turbinate can be readily snipped off with scissors. Bony hypertrophies yield to the saw or trephine. The spoke-shave of Carmalt Jones has given rise to a vast amount of discussion ("American Year Book," Gould, 1898, p. 871), but the cases that require such radical treatment are few. Dundas Grant (*Jour. of Laryngol.*, May, 1897) advocates anterior turbinectomy, making an incision with strong scissors, and completing the operation with a snare. Posterior hypertrophies can be removed by the cold snare. It would seem that eucain would be preferable to cocain, as a local anesthetic for this operation, as it does not cause so much contraction of the tissues (L. A. Somers, *Therap. Gazette*, Jan. 15, 1897). Preston M. Hickey (*The Phy. and Surg.*, Detroit and Ann Arbor, January, 1898), modified the Jarvis' snare by drilling a

hole one-fourth inch from the end of the canula and passing the loop through it to grasp the posterior hypertrophy more readily. L. A. Coffin in the current *Laryngoscope* described an ingenious syringe for injecting monochloracetic acid into posterior hypertrophies via the mouth.

Submucous cauterization by a lance-shaped electrode (Blondian, *Jour. Laryn., Rhin. and Otol.*, December, 1896), avoids the liability of synechia formation. D. Bryson Delavan (*Laryngoscope*, August, 1897) advocates submucous incision with an ophthalmic knife. None of these methods are as satisfactory in the average case as the method of linear cauterization described in the consideration of intumescent rhinitis. When deflections or spurs of the septum encroach unduly upon the normal cavities the removal of excessive cartilage and bone, and straightening the deflection become necessary. Submucous thickening on the sides of the vomer causes obstruction and is readily reduced by linear cauterization.

CAUSATION THE FACTOR IN TREATMENT.

Read at a meeting of the Portland Medical Society, March 1898.

BY ERNEST F. TUCKER, M.D.

PROFESSOR OF GYNECOLOGY IN THE MEDICAL DEPARTMENT OF THE
 OREGON STATE UNIVERSITY.
 PORTLAND, OREGON.

The instinct of self-preservation is probably the strongest characteristic which we see exhibited throughout all the animal kingdom; nor does this tendency of living things to remain alive seem to be entirely due to an instinct, but there seems to be a constant effort on the part of the tissues themselves to prolong and preserve that series of phenomena which we call life, entirely independent of any volition on the part of the individual. We find this effort displayed not only in the animal kingdom, but in the vegetable as well. We see the seeds of small plants and vines, having taken root in unsuitable places, sending out their shoots through cracks and chinks in walls to gain the sunlight; the roots of trees curving around rocks and obstacles, and even displacing these by the exertion of considerable force, to reach the rich soil below. Nor does nature alone seem to tend to the preservation of the individual, but by her mysterious and manifold methods of reproduction apparently does all in her power to perpetuate the existence of the species. I say apparently, for if that loop-hole was not left it might be difficult to explain the certain death that finally overcomes each and every living thing, gradually causing whole species and even classes to become extinct and to disappear from the face of the earth, without casting

doubts on the sincerity or ability of nature to carry to a successful issue the plans she has laid out.

As far as we know, all living bodies can be resolved into a certain number of chemic elements, which belong distinctively to the mineral kingdom, to the absolutely physical nature. The mineral existed before the living world, and in some incomprehensible manner, life made its appearance on the earth. If we could regard life as a form of motion, it would not seem to be going too far out of the way to apply Newton's law to the series of phenomena which make up life. A body at rest tends to remain at rest; a body in motion moves with a uniform velocity in a straight line unless acted upon by some external force to change its condition; in other words, life having once started tends to go on as such until acted upon by some external force, which is incompatible with it. Could we by any means determine what force or forces interrupt life we would be in better condition to try and contend with them. If a cannon ball fired from some huge gun meets with no obstruction in its path it tends to keep on going in a straight line, only impeded in its course by the force of gravity, which, acting on it continually, finally brings it again to a condition of rest. It seems not improbable that there may be some similar force which acts on the living individual from the very moment of conception to the time of death.

As physicians, self-appointed custodians of the public health, whose professed aim in life is not only to ward off the accidents with which our lives seem to be beset, but to do all in our power to preserve and prolong life, it behooves us to inquire into the causes which bring about its cessation.

Let us inquire, first, what seem to be the causes of death in the natural course of events? By this I mean what is called death from old age, not the immediate cause, but the conditions which have brought about the opportunity for the occurrence of the immediate cause? What differences in structure would we find in the body of an individual having died of old age, from those to be found in the body of a new-born child, more than those of size and weight? As far as we would be able to see with the present means at our command, the main difference would be found to consist in a great increase of the fibrous structures of the body over the cellular elements, which are so richly developed in the very young. Again we see the same difference existing between the first tender shoot which makes its appearance above ground in the spring and the old and wind-battered tree, which, like every other living thing, is obliged to meet its final fate. We find this increase of fibrous tissue to be located principally in the walls of the arteries and in the immediate neighborhood of the capillaries, particularly among those which ramify throughout the glandular organs of the body, as well as among the nervous structures. We find, in other words, a more or less generally disseminated sclerosis. On the integrity and functional activity of the blood vessels the nutrition of the tissues depends. The food that we take into our mouths, after being acted upon in the alimentary canal, is either directly absorbed into the blood, or poured as chyle, directly into the blood vessels, by means of which it is carried and distributed to all the tissues of the body, where each takes what it is most in need of and gives up that which is either necessary to some other tissue, or which is to be excreted from the body as useless or even harmful to its functional activity. This increase

of fibrous tissue in the blood vessel walls must necessarily interfere with the nutrition of all the tissues of the body, impairing the function of all the glandular structures by offering an obstruction or interference to the normal interchange of product between the tissues in the blood vessels and those outside, and it is further possible that the increase in the fibrous reticulum of the glands themselves, through which the capillaries mainly pursue their course, may operate by producing atrophy and consequent diminished activity of the glandular epithelium, by an encroachment on their territory.

When the ovum of the female becomes fertilized by the absorption into its interior of the male spermatozoon we see the original cell split up into two cells, then into four and so on, without there being any particular difference apparent in these cells, until they begin to arrange themselves into layers, when three distinct portions become differentiated from each other. From the two external layers are derived all the epithelial tissues of the body as well as the nervous structures, in other words, the chemically active tissues of the body and the nervous tissues which preside over the co-ordination of these functions; while the middle layer gives rise to the connective tissues, or those tissues which have a more purely mechanical function, with the one startling exception of the sexual organs, whose importance in the production of the future generation must not be overlooked. In the middle layer what is known as the *area vasculosa* makes its appearance, which is supposed to be the beginning of the vascular system, and from the endothelial cells or plates, which form the inside lining of the vessels, the first formation of fibrous tissue takes place, and with the advance and spreading of the blood vessels this tissue is carried along throughout all parts of the body, and it seems fair to suppose that the fibrous reticulum, which makes up the scaffolding of the glandular tissues, is derived directly from the capillaries themselves. Thus we see that from the very beginning of life a tissue is being formed which, in the absence of any other accident, will eventually bring about the cessation of life, just as in the case of the cannon-ball, the same force of gravity acting on it from the start, in the end brings it to a period of rest, providing no other obstruction intervened. Granting the preceding to be facts, it must follow that any thing which increases the tendency to the formation of fibrous tissue hastens death, while anything which diminishes this tendency must act to prolong life.

In Dr. Meigs' book on "The Origin of Disease," the importance of fibrous tissue in the blood vessels, as a causative factor of disease, is particularly dwelt upon, and if I understand correctly the philosophy of this book, it is to teach us that most chronic diseases are simply premature old age, and the consequent necessity of our consideration of the patient himself as an entity in our treatment of him, instead of directing all our efforts to subdue symptoms due to a local disorder, which may be only due to the outcropping in one particular organ of a process really widely disseminated throughout the body. Dr. Meigs classifies all diseases as arising from either intrinsic or extrinsic causes. If I might hint at a classification, I would suggest that all diseases arise from either infection or disorders of nutrition. Dr. Meigs' classification, as far as the extrinsic causes go, is simple enough, but it seems that the intrinsic causes might be open to

doubt. For instance, an alcoholic subject who dies from cirrhosis of the liver, dies from an intrinsic disease brought about by an extrinsic agent, the alcohol. In the classification which I suggest, cirrhosis would naturally come under the head of a disorder of nutrition, just as old age would, whether it is allowed to come on by itself, as a natural result of the forces at work, or whether it is hastened by an extrinsic cause.

Infectious diseases tend to get well of their own accord; that is, the inherent forces of the tissues themselves are generally sufficient to overcome the infection and prevent any great disorder of nutrition, where the infection is not too great. Where the infection is too great, disorders of nutrition are produced, and we find the tendency toward the production of fibrous tissue increased, as we see well illustrated in the sequelæ of scarlet fever, typhoid fever, tuberculosis and other diseases. Everything seems to prove that syphilis is undoubtedly an infectious disease, and yet one of its most startling anatomic features is the increase of fibrous tissue, which suggests the doubt as to the complete curability of the disease. An individual may be cured of all his symptoms, he may be cured of the contagion, he may have healthy offspring, but is it not probable that his life is shortened by the disease, and if so, can it be said to be truly cured? In the business carried on by a life insurance company, medical knowledge would seem to find its commercial value, and the unwillingness of such companies to accept syphilitic risks, shows by experience that life is thereby shortened.

In regard to infectious diseases, I have always had doubts that in the microbic theory of disease, the story was more than one-third told. The schizomycetes, to which the so-called pathogenic bacteria belong, are a part of the vegetable world. Vegetable life is dependent first on the seed, secondly on the soil, and thirdly on the climate. A cocoa-nut will not grow and bear fruit in the arctic circle, and we know that certain infectious diseases, which flourish in the tropics, do not occur spontaneously in the temperate zones. The microbes furnish the seed, the tissues of our bodies the soil, and surrounding circumstances may play the role of climate in many infectious diseases. Syphilis is a disease which particularly affects the human race. I believe that there is no authentic case of its successful inoculation in the lower animals, as demonstrated by the consequent symptoms beyond a reasonable doubt. All animals do not respond alike to the action of pathogenic bacteria, some species, so far as we know, being absolutely immune to certain bacteria. This may be a question of soil. Two individuals may be exposed to smallpox and only one of these contract the disease: scarlet fever breaks out in a school, all the children are exposed, but only a limited number are attacked. May this not be owing to some condition present in the tissues of the individuals which may take the place of climate. Experience and statistics have always seemed to show that some diseases appear to be hereditary, and again to refer to the opinion of life insurance companies, these companies are always careful to inquire very thoroughly into the family history of an applicant before granting him a policy. Can not this apparent inheritance of disease be explained on the ground of inheritance of the soil, just as we inherit the outward configuration of our parents, without making it necessary to inherit the

disease itself, which seems to be contrary to physiologic laws.

A few years ago the practice of medicine was based almost entirely on symptomatology, which seemed to be an advance over the older empirical method. Today we seem to be in an anatomic age, in which treatment and classification is based on structural change, a much greater step in advance, but the one to be hoped for in the future must be based on causation, for that attacks disease at its origin and results in prophylaxis, which, if it could be carried out, would abolish the existence of disease. And already what tremendous strides have been made in this direction, so far as infectious diseases are concerned! Where the seeds of the disease can be absolutely excluded, the soil and the climate are of less importance. Puerperal fever has almost disappeared; septicemia as a sequel to surgical traumatism, is now very rare, and with still further improved methods, should become obsolete. But we must not forget that microbes are an invisible foe; that they are widespread in nature and can not under all circumstances as yet be combated by either mechanical or chemie means, and it is here where soil and climate assume their importance. If we could only render the soil unfertile, the climate unsuitable, the mere presence of the seed would not cause us much annoyance. If we could only see how the tissues themselves combat infection, we could then, perhaps, aid them in their battle. Let me take a simple example. An acute gonorrhea is an infectious disease; its most objective symptom is a discharge of pus from the urethra; this discharge of pus is an effort on the part of the tissues to rid themselves of the disease; an increased flow of blood is determined to that part of the urethra attacked; quantities of leucocytes are thrown out; the superficial epithelial cells, which are first attacked by the gonococci, are thrown off and passed out of the urethra; so long as the discharge persists we believe the disease to be present; our object, then, should not be to stop the discharge, but to assist the tissues, and that is just what the modern treatment of gonorrhea attempts by the use of germicidal irrigation; even the so-called abortive plan, the benefits of which are still in doubt in the minds of most surgeons, has the same object in view, to aid in the desquamation of the diseased cells. What we have yet to learn in many conditions is which symptoms are the result of effort on the part of the tissues to combat the infection, and which are caused by the victory of the infection over the tissues; that is, which symptoms to encourage and which to overcome. Even pain is not always to be overcome, as it often acts as a salutary warning.

As to the diseases arising from disorders of nutrition, whether they all give rise to the production of fibrous tissue or not, though there seems to be very good evidence that they do, directly or indirectly. We have seen that these changes are in some way connected with the blood vessels. To explain what I have just said, let me state that in the light of recent investigations by some of the most noted pathologists, there seems to be good ground for the belief that many of the so-called degenerations, such as mucoid, colloid, hyalin, amyloid, etc., are preceded by or dependent upon the formation of fibrous tissue. We have seen that this fibrous tissue about the blood vessels is a constant accompaniment of old age, and it has been shown almost conclusively that it is pro-

duced by the endothelial plates lining the blood vessels, by the intima and not the adventitia. The studies of the changes which take place in the capillaries is very much more difficult than those which take place in the larger blood vessels, owing to the post-mortem changes which seem to occur almost immediately in the endothelial plates, of which alone the walls of the smallest capillaries consist, but from the fact that it seems probable that the fibrous network of the glandular structures owes its origin directly to the vessels which ramify through it, any increase in this fibrous tissue must be produced from the endothelial lining of these vessels, and traceable perhaps to some change or irritation which has taken place in this endothelial lining. We know how readily adhesions are formed as a result of any irritation to a serous membrane, serous membranes being covered with endothelial cells identical with those lining the blood vessels, and adhesions consisting of fibrous tissue. Now if we could account for any irritation to the endothelium of the blood vessel walls, we might perhaps be able to account for the production of sclerosis. As the blood is the only tissue which is constantly in contact with the endothelium lining the blood vessel walls, and as the blood is constantly changing its composition, according to the amount and variety of food which is directly poured into it, it would seem rational to find the source of irritation which gives rise to the production of fibrous tissue, to reside in our food itself. In other words, it is indirectly our food which eventually kills us. In the vegetable world we see the same thing among bacteria during the process of putrefaction. At first we have only aerobic bacteria, which give rise to the production of carbonic acid, which finally encompasses their destruction; these are followed by the so-called facultative bacteria, which are both aerobic and anaerobic; these are again followed by anaerobic ones, and each finally disappears by the products of its own chemie changes. We are at once faced with the terrible proposition that that which is absolutely necessary to our existence eventually brings about our destruction.

As I stated in the beginning of this paper, all living bodies are resolvable into their chemie elements; that is, our tissues are made up of a not very large number of chemie elements, whose molecules are held together in such peculiar arrangement that they are capable of exhibiting those phenomena which we are in the habit of calling vital. Could we increase our knowledge of the chemie changes which go on in the cells during absorption and elimination, and of the consequent physical changes which take place, we would be in a better condition to contend with disease, and I believe that it is along these lines that our greatest discoveries will probably come. And perhaps it may be eventually proven that the same physical laws which govern the movements of the planets, govern what we are pleased to call vital phenomena.

If we look over the list of diseases which we are able to cope with successfully by the use of medicine, diseases in which we would all agree upon the treatment, malaria and syphilis stand out prominently. Upon what is their treatment based? Empiricism pure and simple. Quinia was used long before the discovery of the plasmodium malariae. What the future may hold for us, when time has been able to sit in judgment on the results of serum therapy, and treatment by animal extracts, it is yet too early to say. Surgery would undoubtedly claim for itself the great-

est advances, but if we sift down the facts will we not find that those advances have been more in the line of possible mutilations than in the cure of disease? The successful removal of a woman's stomach in its entirety is undoubtedly a great surgical feat, but was not its removal caused by a confession on the part of the surgeon of his inability to cure the disease. Far be it from me to in any way minimize the untold benefits which have been enjoyed by suffering humanity, as a result of the hard work, the deep study and the combined efforts of all who belong to the medical profession, and to be a member of which I consider myself honored, but it seems to me that it is sometimes healthful to stop and consider what we are really doing; not to rest too comfortably on our laurels already obtained, but by a just and honest view of our possible shortcomings, to remember that there are new fields to be cultivated, new glory to be won in our everlasting battle with disease, and that each one of us, however humble we may be, may by diligent work, thought and observation, be able to add our mite to that grand sum which makes up the total of human knowledge.

A RATIONAL METHOD OF RELIEVING ASPHYXIA IN THE NEW-BORN INFANT.

Read before the Florida Medical Association, April 27, 1898.

BY S. STRINGER, M.D.

BROOKSVILLE, FLA.

I desire to call the attention of the medical profession to a method of relieving asphyxiated new-born infants which I do not think has been presented to their notice heretofore.

I do not claim for this method that it is novel, unique, etc., but that it is based entirely upon chemic and philosophic principles and, like many other facts in our profession, is the result of accidental discovery.

We know that in the asphyxiated infant, unless the blood becomes oxygenated very soon, the child must die; we know that from several causes the sensorium has become so deadened or blunted as not to respond to the irritation of the atmospheric air, the application of water or other methods of inducing respiration; yet fetal life still remains and would continue were it not that the placenta has become detached and thereby respiration or oxygenation of the blood, through the medium of maternal circulation, is cut off. Now, if we could maintain fetal life by any method until the sensorium can sufficiently recover to respond to the nervous excitants of respiration we would, in many instances, save the life of the infant.

How this is to be done is the object of this short essay, as well as to relate the circumstances which led to the discovery thereof.

A few years ago I was called to see a multipara in labor and was told she was in about her fifth month of pregnancy. In a few hours she was delivered of a fetus which I thought to be close to the age indicated. The fetus, membranes and placenta were all delivered by the same effort. Nothing unusual having occurred, the fetus and envelope were laid aside till my departure, when I had it placed in some cloths and rolled up to carry with me for the purpose of saving it as a specimen, but, it being late at night, I deposited it till morning, when I proceeded to examine it and, to my astonishment, found the fetal circulation still going on, with pulse at wrist very perceptible. This was several hours after birth.

Here was a case of fetal circulation, to my mind, carried on by the aeration of the blood through the medium of the placenta exposed to the atmospheric air.

In contemplating this case it occurred to me that this information might be utilized in cases of asphyxia in new-born infants, and I resolved to try the first case that came under my care.

At last a case presented itself: a large and well-developed child, of white parentage, and in which the head had been molded into cylindrical form by a narrow pelvis. The child could not be induced, by the usual method of cold application and rolling, to make any effort at respiration. The circulation was still going on in the funis with some vigor, but the deepening of the dark hue of the surface plainly indicated that, unless oxygenation of the blood could take place, death would soon follow.

Already the pulsation in the cord had become feeble and was becoming more so rapidly, when I delivered the placenta, cleaned it of clots and exposed the maternal surface to the atmospheric air. In a very short time the pulsation was perceptibly increasing in force; the livid and death-like hue was being displaced by one of life and health, when it required but a few moments for the restoration of sensibility and process of respiration commenced.

I feel sure that had the placenta remained in the os uteri or vagina, excluded as it was from atmospheric air, death from asphyxiation of the child would certainly have occurred.

Several subsequent cases have proven, to my mind, that this simple and rational plan of restoration is preferable to all others; and I will ask, Why not? Does not the blood become rapidly oxygenated when exposed to the air even in an open vessel? Have you not seen venous blood reddened in a few moments after exposure to atmospheric air? Then, why not when exposed to the air by osmosis, through the irregular surface of the placenta, where aeration had been going on from the time of the earliest distinct organization of the embryo?

In nearly all cases of asphyxia the labor has been tedious, owing to narrow passage and time to mold the head to the same by the powerful expulsive effort which detaches the placenta and throws it into the os, or entirely into the vagina, as the child emerges from the third stage of labor. Therefore you will find no difficulty in the immediate removal of placenta, should you have a case of asphyxia.

After its removal from the vagina it will be much easier to lift the cord from the neck and examine it for any interference with free circulation and correct the same. The placenta should be spread out with maternal surface cleansed of all clots and membranes so that free access of air can be had. If it becomes necessary, on account of numerous clots, to use water to cleanse the maternal surface, it is advisable to have it warm, as it is remarkable how quickly the use of cold water will chill the child; yet it is but natural to expect such result when you apply cold to so large surface of the capillary circulation as is maintained in the maternal surface of the placenta.

So long as the circulation keeps on through the cord you need not fear for the life of the child, for it is a continuance of fetal life, after birth.

As soon as respiration occurs, which has been delayed as long as twenty-five minutes in some of my cases, the circulation is diverted from the placenta to the lungs, and pulsation in the cord ceases in a few

seconds, when the child should be separated from the placenta as in ordinary cases.

I commend this method to the profession and ask that it be tried where more cases present themselves than are met with by provincial practitioners, when, I am convinced, it will be universally adopted.

I can not omit referring to the great advantages which, it seems to me, must result from the delivery of the placenta in cases of placenta previa, advantages not only to the mother but to the offspring. As the consideration of this subject would require considerable time I will only give a few extracts from the literature on dystocia. Dr. Simpson has collected 120 cases in which the placenta was delivered prior to the birth of the child. Of this number 31 of the children were born alive, 2 were putrid and 87 still-born. I have no doubt but that a large per cent. of the 87 still-born died of asphyxia, in consequence of the retention of the placenta for some time after its detachment. Had it been promptly delivered and exposed to atmospheric air many lives would have been saved.

ALBUMINURIA FROM THE STANDPOINT OF LIFE INSURANCE.

BY MARK A. BROWN, M.D.

CLINICAL LECTURER ON MEDICINE, MIAMI MEDICAL COLLEGE,
CINCINNATI, OHIO.

At the present day, in considering the advisability of accepting a certain risk, the presence or absence of albumin in the urine may be readily regarded as the deciding weight, either for rejection if present or acceptance if not. Certain it is that the examination of the urine for this abnormal ingredient is looked upon by the home office as of such importance that except in industrial insurance, no report will be accepted without definite statements. Nor is this a matter of surprise when we remember the large number of fatal diseases accompanied by albuminuria. In many companies the albuminuria alone is sufficient cause for rejection and the underlying disease, if not entirely disregarded, is at least looked upon as a matter of but small moment. In this manner mistakes are made upon both sides. No greater error can be made than to look upon every case of albuminuria as Bright's disease, unless it is to regard every case not accompanied by albuminuria as not being Bright's.

It has been estimated that about one-sixth of the applications for life insurance (ordinary) are refused, all causes being taken into consideration. At least one-fourth of these rejections are based upon the presence of albumin in the urine. It is preposterous to assume that one twenty-fourth of the number that apply for life insurance are afflicted with nephritis; we must always be on the lookout for other explanations than irreparably damaged kidneys to account for our symptoms. Nor must it be forgotten that albumen may exist in the urine in several forms, of which serum albumin is the most important, responding to the usual rough tests applied by examiners. Again an admixture of urine with substances containing albumin, blood, seminal and purulent fluid, will throw down a white cloud to the heat and nitric acid test just as readily as will a chemical solution of albumin in urine. Here enters a first plea for microscopic examination in all cases where the slightest trace of albumin is found. A small amount of any of the above abnormal admixtures might and, as a matter of clinical observation, frequently does escape

detection on macroscopic examination, yet even such a small amount may cause a slight albuminous reaction, a reaction very like that of chronic interstitial nephritis, the disease which so slowly but surely carries off such immense numbers of the race. One's doubts as to the existence of such abnormal constituents as pus cells, blood corpuscles or spermatozoa in the specimen under consideration, will be at once dispelled by a few minutes use of the centrifuge and microscope. When we reflect upon the large number of pathologic conditions which might result in the pouring out of blood or pus, or both, into some part of the genito-urinary tract, especially when we remember the great prevalence of urethritis, simple and specific, acute and chronic, we are not much surprised at the frequency of albuminuria; indeed, we are rather inclined to feel correspondingly encouraged at the lessening of the number of cases of possible Bright's. Of late years the increasing frequency of life insurance among women, while not liable to increase the average of insurance mortality of Bright's, yet certainly must hold its own as regards the ratio of albuminuria. Menstruation, endometritis and vaginitis, would easily maintain the standard. From this it can readily be deducted that uranalysis in a female is not of much value unless the urine is obtained by means of the catheter.

Albuminuria in its present day aspect is divided by clinicians into two types, the physiologic and the pathologic. The former is a convenient head under which to class cases in which the symptom is transient or intermittent, and in which it occurs, presenting no other sign of kidney or circulatory disease. The albuminuria of pregnancy is termed by the adherents of this class as physiologic in a large number of cases; that it is a frequent symptom among women in this condition is admitted by all who have looked closely into the question. Aufrecht reporting as high as 56 per cent. In new-born children albuminuria is common during the first few days of life, but the changes in circulation would readily account for this. Among these intermittent cases, the albuminuria that occurs in bicycle riders is of late receiving deserved attention. Mueller¹ reports eight cases in trained cyclists, in whom, after a fatiguing ride, there appeared an albuminuria which even with the aid of the microscope was absolutely indistinguishable from that of true nephritis. It is interesting to note that after several days of rest the albuminuria disappeared. The urine when examined previous to the ride was free from albumin in all cases but one, while after the ride seven out of the eight showed albuminuria and the majority casts of various kinds. These cases will be referred to again in speaking of the pathologic type. Suffice it to say here that they were regarded as physiologic, by their reporter, on the grounds that the albuminuria was intermittent, disappearing completely on the cessation of the excessive exertion, without apparent damage having been sustained by the kidneys. The ultimate fate of these men might make an interesting contribution to the etiology of nephritis. Vaccination is not infrequently followed by transient albuminuria in subjects who were previously free from the abnormality. And so we could go on adding case after case called physiologic because the albuminuria is transient and is not accompanied by casts. Tyson,² in considering physio-

¹ Muench. med. Woch., 1896.

² Tyson's Practice of Medicine.

logic albuminuria, writes: "The presence of a physiological or functional albuminuria at the present day is generally conceded. By it is meant an albuminuria which is associated with no other symptoms. There are no tube casts or feeling of ill-health. Such albuminurias are often discovered accidentally, especially by examiners for life insurance. Much care should be exercised in concluding upon the nature of an albuminuria suspected to be functional. In the first place it should be small, not exceeding one-tenth the bulk of urine tested, and though it is not necessary that it should be absent on rising, yet it is a strong point in favor of the functional nature if it is absent at this time and present only after some exertion has been made or on taking food. No tube casts should be in the urine, the urea should be in sufficient quantity, there should be no retinal change, no hypertrophy of the left ventricle, no high tension of the pulse, nor even a suspicion of dropsy. *And this condition should be maintained over a considerable length of time before the conclusion is arrived at that we have to do with a harmless functional albuminuria.*" This latter italicised clause practically settles the question as far as life insurance is concerned. Very few applicants will consent to wait patiently for several months, "on trial," as it were, submitting themselves to the inconvenience of frequent examinations of their urine. If they are not rejected immediately they will soon suspect from the delay that there is something wrong with their urine, and will withdraw their application before it is rejected. No, a company must do one of two things, accept or reject; half-way measures will do much to weaken a company.

It is a fact constantly brought out from insurance offices that cases of albuminuria which have been insured show a large and early mortality. These are selected cases, looked upon as of cyclic albuminuria by the examiners, which latter have returned favorable prognoses. Is it not more reasonable, in light of this fact, to regard many of such cases as in the first stage of that organic change which leads to granular atrophy? Take the instance of the trained cyclists referred to above, for example; a frequent repetition of the exercise which was followed by the appearance of albumin and casts would inevitably bring about organic destructive changes in the kidney substance itself; for we know that if an irritative lesion be exerted upon an organ over a considerable period of time newly formed connective tissue will result, to be followed sooner or later by cicatricial contraction. In the infectious diseases, smallpox, diphtheria and typhoid, the presence of albumin in the urine is of common occurrence, and no one attempts to claim that such albuminuria is physiologic, though it may disappear entirely without sequelæ with the cessation of the original disease, and is not always accompanied by the appearance of casts. Here the specific microbe of the disease or its ptomain is said to bring about changes in the circulating fluid, followed by fever, increased arterial tension, and finally by structural changes in the cells of the internal organs. The kidneys participating in this cloudy swelling, as it is called, the organic changes occurring in the delicate epithelium of the tubules and glomeruli readily allows the transudation of albuminous elements from the blood, which would be rejected were its integrity preserved. This is the main principle underlying every case of albuminuria; some interference with the

integrity of that portion of its secreting structure that acts, as it were, the part of a dialyzer—in other words, the epithelium of the tubes. As long as this remains intact, just so long will the non-osmotic albuminous elements be prevented from entering the tubules and eventually the urine; the greater the destruction of epithelium, the greater the amount of albuminuria, provided the tubes do not become obliterated as they do in chronic interstitial nephritis. From this standpoint the pathologist would regard every case in which albumin was present as pathologic, even though pathologic structural changes were few and microscopic. He would look upon any case of transient or intermittent or cyclic albuminuria, not as a physiologic process, but as a pathologic one, in which the ever working silent forces of nature had succeeded in calking the leak, in replacing the diseased or destroyed epithelium; in short, that no such thing as physiologic albuminuria exists: that every case in which this symptom occurs is pathologic and is always accompanied by definite organic nephritic change, though they may be of only microscopic size and are quickly repaired. To quote from Osler,³ "the presence of albumin in the urine, in any form and under any circumstances, may be regarded as indicative of change in the renal or glomerular epithelium." From a life insurance standpoint, one can not but regard the matter in the same light. When we consider the enormous interests often involved and the frequent crudeness of the urinary examinations, the rejection of cases with albuminuria without casts or other symptoms of nephritis can not be looked upon with surprise, though such rejections might add a powerful enemy to the company to say nothing of the direct loss from his premiums.

As shown above, the presence of albumin in the urine means very little in itself, aside from giving us a strong hint for further investigation, for a considerable amount of albumin may be present and the kidney lesion be slight, or we may have other of the genito-urinary organs at fault. We have but one way of thoroughly understanding the condition and that is by microscopic examination. On the one hand we may have no kidney trouble, yet considerable albuminuria; on the other, we may have chronic inflammatory disease of the kidneys well advanced without the constant presence of this substance in the urine. It is of the greatest value for the home office to know what has been found under the microscope, when albuminuria exists.

In that most common of kidney diseases, that slow inflammatory process in which by the contraction of gradually formed new-formed tissue, the kidneys are reduced markedly in size, chronic interstitial nephritis, gouty kidney, contracted kidney or whatever one may choose to call it, the urine usually presents the following changes: Passage of a larger quantity than normal in the twenty-four hours, a low specific gravity, almost without color; in these albumin may be found only after testing several samples of urine and then only in traces. The heart and arteries would next claim our attention. The presence of an hypertrophied left ventricle without valvular disease, combined with a pulse of increased tension, would be significant. Arterio-sclerotic changes in the radials or temporals would be strong evidence of a similar change in the arteries of the kidneys. One of the most valuable points in the diagnosis of suspected

³ Osler: "Principles and Practice of Medicine," 1895, p. 768.

Bright's disease, especially of the form under consideration, is a dilated, tortuous, congested appearance of the retinal vessels; pulsation of the retinal veins is also frequently observed. As mentioned above, the urine may at times be free from albumin, but continued examination will eventually prove its existence. The difficulty lies in the fact that even in policies calling for many thousands of dollars but one urinary examination is made, or if there are two examiners on the case, both obtain a specimen passed at approximately the same time. Undoubtedly, large numbers of cases of beginning atrophic cirrhosis are passed every year in this manner. In the incipient stages of this disease, probably the symptoms above mentioned would not be sufficiently in evidence to provoke comment, unless we except the retinal changes. How few of us, however, outside of specialists, are able to make a satisfactory ophthalmoscopic examination! One interesting fact in regard to the etiology of Bright's disease must not be lost sight of: That the form known as chronic interstitial nephritis rarely occurs before the age of 40. Now what shall we do in cases where an albuminuria has been found or even when albumin is not present? It seems that the only remedy is to have a microscopic examination made in every case in which the application calls for more than a certain fixed sum, say \$2000, provided the applicant is over 40 years of age. Some companies have instituted such a plan when the application calls for a large amount, \$20,000 or over. This is a step in the right direction, but the limit should be greatly lowered. Companies would do well in securing this end to appoint in all cities, in addition to their regular examiners, one microscopist, whose sole work should be to make the microscopic tests whenever required by the amount of the application. Such an examiner would be working independently and would not be hampered in the slightest degree by the influence of agents. He would know nothing as to the other findings in the case and his results would stand strictly on their own merits. In this way, too, statistics would be soon forthcoming from the home offices as to the frequency of albumin without casts, casts without albumin, presence of both albumin and casts, and a satisfactory working basis started. In time we could work backward and the poor unfortunates, from a life-insurance standpoint, who have habitually slight albumin without casts, instead of being universally rejected, be allowed insurance, though perhaps at an increased premium.

FALLACIES IN THE PHYSIOLOGY AND FUNCTIONS OF THE LABYRINTH.

BY M. A. GOLDSTEIN, M.D.

Professor of Otology, Beaumont Hospital Medical College; Consulting Aurist to the Alexian Brothers' Hospital, and to the Sisters of St. Joseph School for the Deaf.
ST. LOUIS, MO.

The great advance made in our knowledge of the physiology and pathology of the external and middle ear during the past decade has far overshadowed, in quality and quantity, the results which have been obtained in the investigations of the internal ear. Perhaps this may be due, in part, to the relative infrequency of diseases of the labyrinth, and the consequent insufficiency of data; perhaps also to the difficulties which often present themselves in making correct diagnoses of many labyrinthine affections.

On the other hand, we have many series of valuable clinical observations on diseases of the internal ear, without being able to determine the pathologic changes which have taken place; again, we have interesting postmortem findings in labyrinthine diseases without the support of proper clinical data. Thus, much of our information on the subject is but the combination of hypotheses and possible conditions, lacking the strength of absolute scientific data and certainties.

Concerning our knowledge of the anatomic and functional changes and the diagnosis of diseases of the internal ear, we are still on the threshold of our subject, notwithstanding the many interesting reports of cases and clinical observations furnished by experienced observers in every section. The physiologic significance of the semi-circular canals has been the subject of considerable difference of opinion, and many of the experimental data now at our disposal are so conflicting that our results have been based on a rather indefinite foundation.

The former theory, that the angles which the semi-circular canals form, arranged perpendicular to each other, thus accounting for their capability to determine the direction of sound, seems to have been entirely discarded. More interest centers about the functions of the semi-circular canals as organs of co-ordinate movement. The fundamental experiments upon which this theory is based, were first performed by Flourens. He repeatedly observed, after division of the semi-circular canals in pigeons and rabbits, considerable motor disturbance, which convinced him that these canals were the central and control organs for co-ordinate movement.

Careful investigators however, operating along the same experimental field, have arrived at decidedly different conclusions. Thus Goltz, Crum-Brown and others, look upon the semi-circular canals as the "organ of the sense of equilibrium"; Cyon designates them the "organ of the sense of space"; Löwenberg refers the symptoms mentioned to a reflex transmission of the irritation caused by the injury to the motor nerves of the thalamus opticus. Opposing these theories, Moos, Böttcher, Baginsky and Tomaszewicz infer that all disturbance after injury to the semi-circular canals proceeds from a simultaneous injury to the cerebellum. Many of these conclusions have been reached by experiments conducted on some of the lower mammalia, and the great variation in the data acquired would tend to establish, even without further proof, the uncertainty and fallacy of these several theories.

Permit me to add my own clinical observations relating to the functions of the labyrinth, which though limited, I have nevertheless been able to repeatedly verify.

In April, 1895, I reported my clinical data of an especially interesting case of exfoliation of the labyrinth. The case was that of a young negro boy, 6½ years of age, who developed a suppurative otitis media after a severe acute rhinitis. After nearly two years of profuse and continued suppuration, during which time no complications had arisen, the patient came under my observation. The unfavorable aspects of the case had now presented themselves. Mastoid infiltration and inflammation were marked, and complete facial paralysis of the affected side was demonstrable. On operation the greater portion of the outer bony area of the mastoid was found to be a softened,

necrotic mass, and could have been more easily ladled out with a spoon than removed with a curette.

In the course of five weeks, five sequestra were successively removed from the temporal bone. The largest exfoliated mass contained nearly the entire bony labyrinth. The cochlea was almost completely exfoliated; the vestibule with the ampullæ were plainly visible, also a considerable portion of the semi-circular canals, together with a honey-combed mass of mastoid cells. After the removal of the last sequester, the patient was convalescing rapidly, and January 5, two months after operation, he was presented at a meeting of the St. Louis Medical Society. He was then bright, active and in good spirits. Three weeks later, a rapid, general decline ensued and the patient died shortly afterward of acute, miliary tuberculosis.

Unfortunately, permission was not granted for a complete postmortem, but, the right temporal bone was removed, and the involved area carefully inspected. Examination of the affected temporal bone, after its removal, corroborated my description of the necrosed and exfoliated areas.

Circumscribing the region of the osseous external auditory meatus, and involving the mastoid and squama, with a radius of about three-quarters of an inch, was a necrotic zone with irregular, but well defined margin. Designating this as the base of a long, cone-shaped canal, we note an axis of about two and one-half inches in length, directed inward, downward and backward, with its apex merging into the Eustachian tube. This cone-shaped sinus, through which the exfoliated bone masses were removed, was lined with quite firm, closely meshed granulations. All landmarks of the osseous meatus auditorius externus and cavum tympanum had disappeared. Of the petrosa, the superior wall and part of the posterior portion of the meatus auditorius internus still remained intact. Examined while fresh, the portion of the nervus acusticus, lodged in the depth of this canal, was to all appearances normal in color and consistency. I desire to especially emphasize this fact to substantiate later observations.

After removal of the bone, the exposed cavity was carefully examined; with special stress laid on the cranial areas in direct relationship to the necrosed bone. On the periosteal surface of the bone still remaining, numerous erosions and irregularities were noted, yet the dura mater at all points was perfectly firm and intact. With the existence of a disseminated and rapidly progressing tubercular process, our anticipations of the presence of a tubercular meningitis might have been well founded; the most careful and detailed search, however, failed to reveal any meningeal lesion whatever.

In the first place, I would offer as a proof of the fallacies of the present accepted theories concerning the functions of the semicircular canals, that this patient walked into the assembly hall of the medical society with a thoroughly steady gait and a perfect sense of direction, walking with head and body erect, and turning to the right or left as indicated by members of the society conducting the examination, and all this while the exfoliated labyrinth containing the cochlea and semicircular canals, taken from his right temporal bone, was lying on the table awaiting inspection.

The postmortem examination substantiated my conclusions that not only the osseous semicircular canals

had been entirely exfoliated, but no vestige of even a membranous labyrinth remained, so we are justified in concluding that it also had been destroyed.

Walking and standing tests were repeated frequently; varying the same in every conceivable way by blindfolding the patient, testing with eyes closed, permitting the patient to walk under the influence of loud noises, etc. The results were always positive, the gait firm and steady, position of the head erect, and the power of equilibrium and sense of direction preserved to a nicety.

In presenting these facts it is not my purpose to promulgate any new theory concerning the functions of the labyrinth, but to emphasize the fact that many of our ideas thus far conceived, will admit of decided revision.

Concerning the functions of the cochlea, much of our present information is based on hypotheses. By the labors of Helmholtz, Corti, Ranke, Hensen, Hasse, Exner and others, great progress has been made in establishing the functions of the delicate structures of the labyrinth, yet even Helmholtz, whose pioneer work in the physiology of the ear has contributed so many interesting and valuable data, admits the possibility of error in these observations.

In the literature of otology, necrosis of the cochlea or part of the bony structure of the internal ear is not of infrequent occurrence, but an exfoliation of the entire labyrinth in one piece is indeed very rare.

Sexton, Gruber, Guye, Bezold, Rueda and others have seen and reported cases where exfoliation of the cochlea alone has not been attended with total loss of hearing on the affected side. Sexton even emphasizes his observations by the statement: "I fancy no one disputes that in one of my cases marked hearing remained." These cases are, in themselves, substantial clinical evidence that the cochlea is not an absolute essential to hearing. In these cases, however, only the cochlea had been exfoliated, the other structures of the labyrinth remaining intact.

I desire to advance one step farther in the conclusions thus far reached. I maintain that in the case which I have reported, of exfoliation of the entire labyrinth, a very fair degree of hearing was retained in the affected ear, and herewith present for consideration the tests and observations recorded. I have been thoroughly cognizant of the difficulties and responsibilities attending an effort to substantiate so radical a statement, and have necessarily adopted the most careful methods and delicate tests to convince myself of the accuracy of my conclusions. The most serious obstacle to contend with was the exclusion of the healthy ear from the sound tests which were instituted. In the majority of the tests made I adopted the method suggested by Dennert and Lucae, with modifications. In determining what degree of sound perception still exists in an affected ear in a case of one-sided deafness, the healthy ear of the patient is stopped, turned toward the source of sound and the tests then made, the affected ear being alternately opened and closed. Whatever difference in the hearing then elicited, is attributed to the affected ear.

A more delicate modification of this method has been successfully used by Burnett. The patient is so placed that the affected ear is toward the operator. The healthy ear (not the ear to be tested) is plugged. With the affected ear open, hearing tests are then instituted. Having thus reached the apparent limit of the hearing power of the affected ear, that ear is

then closed, and the tests continued. If the closure of the deaf ear causes no difference in the hearing distance already obtained, it is fair to conclude that whatever amount of hearing exists is not due to passage of sound through the external auditory canal of the affected ear turned toward the test. In such a case the conclusion must therefore be that sound has reached the brain through the agency of the healthy ear. If, however, the stoppage of the affected ear is accompanied by an absolute inability to hear sound tests, it is again rational to conclude that this difference in the hearing power must be attributed to the affected ear. Thus, the final conclusion: "Whatever is heard just as well with the deafer ear stopped as when open, the better ear remaining stopped throughout the testing, must still be heard by the better ear through the head; but whatever is heard with the worse ear open, the good ear being stopped, must be attributed to the worse ear."

The question might be asked, Why can not sound be conveyed to the deaf ear through the head, if it is conveyed to the better ear which is stopped and turned away from the sound source? The reply would be that an ear which, either when stopped or open, perceives no difference in sound conveyed by the meatus, is not sensitive enough to hear sound conveyed to it through the head.

In the consideration of the case at hand, bone conduction tests by aid of tuning forks were excluded, as they were deemed less delicate for a differentiation than aerial sound conduction. Furthermore, as our dealings were directly with an exfoliated labyrinth, the tuning fork, relative to bone conduction, was practically of no value.

The following tabulated notations will indicate clearly the conclusions reached in hearing tests of the affected ear:

HEARING TESTS.	Hearing capacity with both ears open and closed.	Hearing capacity with affected ear open and good ear closed.
Loud conversation.	300 cm.	900 cm.
Whispered conversation.	30 cm.	90 cm.
One hundred and fifty centimeter watch.	5 cm.	15 cm.
Pollitzer's accoumeter, designated by patient as a loud ticking watch.	15 cm.	35 cm.
Galton whistle; pitched high.	30 cm.	60 cm.
Differentiation in sound of C from C ⁴ tuning fork.	8 cm.	35 cm.
Musical notes of a loud sounding harmonium.		
Differentiation of C (3d octave) from C (5th octave).	35 cm.	90 cm.

In the execution of the enumerated tests the patient was blindfolded; the plugging of the meatus was done by a competent assistant, the forefinger being used as a tight plug. Taking into account the age of the patient and all tendencies to a possible misrepresentation of the hearing capacity, the tests were repeated at frequent intervals with many variations, yet the tests proved doubly valuable, owing to the demonstrable accuracy of the patient's statement.

Thus, the conclusions which have been logically and carefully reached tend to establish the fact that this patient, with an exfoliated labyrinth, still retained partial hearing faculties in the affected ear.

Pathologically, we deal in this case with a destruction of the peripheral or terminal filaments of the auditory nerve, as indicated by necrosis of the cochlea and semicircular canals.

Physiologically, we know that the auditory nerve, when stimulated either at its origin, in its course or

at its peripheral terminations, gives rise to sensations of sound. We also have the report from several authentic sources that after exfoliation of the cochlea considerable hearing power may be retained by the affected ear. As the peripheral apparatus is hereby destroyed, how is the function of audition carried on?

We know that perception of light does not depend entirely on the presence of rods, cones and lenses; walking along in a dark corridor and suddenly coming in contact with some external object causes an impression of a bright flash of light. Nor does the sensation of taste depend exclusively on an exercise of the physiologic functions of the tongue; when a galvanic current is applied to the face we readily experience a metallic taste in the mouth.

We even speak of "seeing sounds" where the impressions of musical tones are interpreted by certain individuals as colors of variegated hues; and of "nasal vision," where the nose, in part, performs the function of the impaired or absent eye.

I would illustrate with these examples that even the nerves of special sense may have compensatory functions. Why then can there not be such compensation of the nervus acusticus?

In the postmortem examination it was found, macroscopically and microscopically, that the portion of the auditory nerve still retained within the internal auditory canal was, to all appearances, normal and healthy.

Is it not possible that sound waves could have been conducted through the large sinus left by the removal of the several sequestra, and could thus have been impinged directly on the stump of the exposed auditory nerve and transmitted directly to the brain?

3702 Olive Street.

SOCIETY PROCEEDINGS.

Associated Health Authorities of Pennsylvania.

*Fifth Annual Meeting held at Lancaster, Pa.,
May 18 and 19, 1898.*

FIRST DAY—MORNING SESSION.

Prof. E. O. LYTE, Principal of the Millersville Normal School, made an address of welcome, which was responded to by Prof. G. G. Groff, President of the State Board of Health, who was introduced by First Vice-President Crosby Gray of Pittsburg, Superintendent of the Bureau of Health of that city.

The first paper was by Prof. R. C. SCHIEDT of Franklin and Marshall College, on

THE RATIONAL TRAINING OF CHILDREN A PROBLEM IN PEDAGOGIC PHYSIOLOGY.

The subject was treated exhaustively, not only from the standpoint of the teacher, but from that of the psychologist and the physiologist. He said that his results differed from those obtained by the German and French psychologists and because of the difference in the children of different nationalities. The American boy is superior to any other on the face of the globe. The Professor has had splendid opportunities to observe the difference in the physical condition of children through his connection with various German institutions. It is generally agreed that we are living in an age of unusual activity that has placed its stamp upon the children of the land. Education is looked upon as a panacea for all the ills of the body politic is heir to, and the responsibility of the future of the race is placed upon the schools. As a matter of course, in a land like ours, we are confronted with a maze of conflicting opinions. But is it actually true that the children of our age are in such a deplorably nervous condition? I am inclined to think not. I have made extensive experiments in Berlin and America to study the nervous condition of children. By means of a machine I measure the degree of fatigue under which any individual may be suffering. In Germany the best

pupils exhibited only the slightest trace of nervousness. Some nervousness was traced to the use of alcohol and an insufficient amount of sleep. Only 23 per cent. of those examined were refreshed by gymnastic exercises. In the schools of Lancaster, the experiments showed 15 per cent. without any nervous fatigue. These experiments were made on different days so as to obtain different atmospheric conditions, with widely varied results. On a clear day 90 per cent. of the boys showed a good condition before the school opened. At 3 P.M. 15 per cent. were more refreshed than when they started to work in the morning. But 7 per cent. were unaffected by atmospheric conditions. The large number of 43 per cent. exhibited abnormal fatigue. The experiments on the whole were very gratifying as far as the children of Lancaster were concerned. These show that alternate periods of study and relaxation, as is the practice in Lancaster, is the best plan to pursue. The 43 per cent. showing abnormal fatigue should have more systematic out-door exercise, otherwise the results can not be satisfactory to teacher or pupil. Intellectual activity is a prime essential in the development of a sound and vigorous body. He advocated, most earnestly, indulgence in out-door exercise; would abolish the afternoon session and have a long morning session with a number of recesses. With the introduction of manual training in all schools each child will thus be afforded a better opportunity to develop its individual tendencies. In the class room the pupil is but one of a dozen, and the only virtue adduced therefrom is obedience, which the child should have learned at home. Physical exercise should be divided into three classes, muscular, cutaneous and inspiratory.

A discussion followed by Drs. Benjamin Lee, Secretary of the State Board of Health of Pennsylvania, J. Madison Taylor and S. D. Risley of Philadelphia, each commending and agreeing with the points made by the reader.

Miss DORA KEEN, Chairman of the Committee on this subject appointed by the Public Educational Association of Philadelphia, had prepared a paper on

MEDICAL INSPECTION OF SCHOOLS,

which was read by Dr. J. M. Taylor.

In October, 1896, Dr. C. F. Robert, Sanitary Superintendent of the New York Board of Health, sent a communication to the board, setting forth his belief that the greatest source of the transmission of infectious and contagious diseases among children was through the contact with one another at school, and that this transmission would best be overcome by systematic daily inspection of the schools by medical inspectors. Such inspection had its first trial in the parochial schools of Philadelphia some years ago, and was abandoned owing to a mistaken opposition. This city was ahead of the times. Boston soon seconded her, and now New York and Chicago have adopted this plan. It has proved the value of the work, and abroad Brussels has adopted it, and Boston is getting the credit of it. Providence, Baltimore and Milwaukee are agitating the question. Only yesterday, the Philadelphia Board of Health took the proposition of the Public Educational Association into consideration, referred it to its sanitary committee, and appointed a hearing for May 31. While the inauguration of this work comes properly within the function of the city boards of health, with whom it lies to organize and conduct the work, yet no less does it claim the interest of physicians and teachers. To assure themselves of the value and necessity of the system the Boards of Health of New York and Boston conducted preliminary investigations. The latter published tables by months of all cases of diphtheria in nineteen years in that city. There was a variation of 1600 cases reported in any two months and the smallest numbers were during the summer vacations. The total for nineteen years was 3339 cases in January and 2537 in June, as opposed to 1765 in August. So with scarlet fever. Records for twenty years showed 3107 cases in January and 1885 in June compared with 1208 in August. An example of the protection of the community by the Boston plan was shown in 1897 in an epidemic of diphtheria. A primary school of forty pupils had fourteen attacked in eighteen days, all from one room. Seven were discovered by a medical inspector, three of these by cultures. All suspicious cases were dismissed and recommended to the care of the family physicians. The next morning everyone was examined, many cultures were taken, the class was dismissed and the rooms disinfected and cleaned. For ten days after the return to school everyone was examined when first the class assembled in the morning, and no child absent with any suspicious symptoms was allowed to return till it was proved safe by a negative culture. The result was that not a single case resulted beyond those known to have been infected at the time the epidemic was discovered. Similar experience occurred with scarlet fever in the service of the same inspector shortly after, in which all

eleven cases resulted from the presence of one pupil, whose illness had been diagnosed German measles. In New York the best results were obtained by securing a list of the absentees where a case of contagion had occurred, and visiting the families to learn the cause of absence. Eighty-five families visited showed fifteen cases of scarlet fever and nineteen of diphtheria, in which the first case was a school child. The statistics seemed to show that many cases of diphtheria went unnoticed, and the same to a lesser extent with scarlet fever. Children sent home with a "sore throat" fail to call in a physician, and return to school when feeling well. Thirteen out of twenty cases would have remained unknown if the absence list had not been examined in one report of scarlet fever. Of these, four did return and would have remained to spread contagion if they had not been known as dangerous. Others were preparing to return, so that the epidemic would have been indefinitely prolonged. In regard to measles, seventeen cases were reported, and upon investigation twenty more were found, which from ignorance had not been reported. Of these, twenty-two had contracted it in school. This evidence was so convincing that application was made for the appointment of a chief medical inspector, with a staff of 150. In both Boston and New York school inspectors are separate from regular medical inspectors. The duties of the school inspector are "to visit the schools of his district daily at the opening of school, examine all pupils whom the principal has found to be ill or complaining, and advise the teacher concerning them; to keep a record of the diagnoses for the custody of the principal, and to forward daily and weekly reports to his chief. He never encroaches upon the rights of the family physician. He is simply to examine all children that appear to be ill, point out the need of treatment, and to exclude contagious cases from the school. A courteous note is sent to the family physician stating the cause of exclusion. Blanks, wooden tongue-depressors, culture outfits, etc., are furnished at the central office. The inspection consumes very little time and creates but little confusion. Results: In Boston, 1896, 8964 were examined, 1156 too ill to remain in school; 3934 were suffering from oral and respiratory diseases, 267 from specific contagious diseases.

In one school parasitic diseases of the head existed in 74 per cent., and 7 per cent. were very badly affected. In Chicago so much benefit resulted from the inspections that it was determined to continue the work to the full extent of the resources. During four months 350 inspections of 233 schools were made, 1417 cases of diphtheria and 306 of scarlet fever located. In New York 63,812 were examined in the first three months, 4183 or 6 per cent. were excluded for contagious diseases. Parasitic diseases of the head numbered 2627; contagious diseases of the eyes 702. Among a large number of people no dread of measles or scarlet fever is felt and such often oppose the means of prevention.

On the side of defective sight and hearing, preliminary and unco-ordinated tests are all that can be reported. This field is an important one, yet no city has yet co-ordinated that work with general medical inspection of schools. The work is worth doing well, but it is a severe piece of drudgery. One specialist says that 300,000 examinations have had very little scientific value. As for methods, it has been shown that a fairly complete examination of both eyes of an individual can be made in three to five minutes. A part of the work can be done by an assistant. Conveniences for the examination can be usually arranged at the school, and may be either in or out of school hours. One thousand children may be set as the limit of one man's work, pretending to be thorough. Many of the alleged studies on record can be used to prove anything and really show nothing. Looking at the results thus far, we find that awakened interest of the community has already greatly improved the conditions for the school child. Nevertheless, near sightedness has not decreased. Large classes and the pressure of changing methods of instruction, force the teacher to a somewhat wholesale treatment of pupils, while the recent investigations of 2,000 children of the Philadelphia Teachers' Society for Child Study purports to show 54 per cent. suffering from defective vision. Some cases were so serious as to interfere with the intellectual development of the pupils. An interesting statement of results showed a majority were not aware of any defect of vision and the strain on the mechanism of the eye was going on unnoticed. It is a system of education fruitless of real development that attempts to force all children alike, regardless of the fitness for work of the particular child. Philadelphia's contribution to this branch was made by a committee of the County Medical Society under the direction of Dr. S. D. Risley, in 1878. He received the hearty support of the Board of Education and the community. Twenty-six hundred examinations were made in two years. "Many a

school boy idle only at his books, dull only in the recitation room, is so because he finds the continued use of his eyes a painful task," and near-sightedness comes to affect his mental habits and moral character as well as his physical constitution. Extended observation in Europe showed that this trouble increases steadily as the education goes on. In America, it rises from 3.5 per cent. of children 8 years of age to nearly 20 per cent. at 17½ years. In Germany, perfect hygienic conditions of hours, seating and lighting, failed to arrest the increase. The committee of the County Medical Society sought to answer the question, To what extent are our educational methods and manner responsible? The following conclusions were reached: That the possible presence of defective vision should be excluded by examination before entering school; that children enter too young; that the course of study should be so chosen and arranged as to avoid protracted use of the eyes at a near point; that the system of term examinations should be entirely abandoned; that text-books should be of good paper and large type; that the method of writing should be optional; that since numbers of the pupils with the weakest eyes drop out after the first few years a more elastic curriculum that would admit of steady though slow promotion is advisable.

The suggestion of a study of the individual needs of the child brings us to the conscious realization of the opportunities the inspector will see open to his intelligent study. While his primary duty is to seek and recognize signs of contagion, he may find a useful line of study in the incidental detection of defective children. The modern plea for individualism in education seeks to adapt conditions to the child, not the child to conditions. Let us, therefore, look to the results of scientific medical inspection, if we would know how great is the need for special schools for special classes. Europe has special schools; our National Education Association has a branch on special schools, and these already exist in Wisconsin, Chicago, Boston and Providence. Mr. Alexander Graham Bell makes a plea for special schools for the deaf with small numbers and centered at convenient points. Chicago reports eight public day schools for the deaf. Let us hope that an intelligent public sentiment may in time recognize that facilitated work and results to both teacher and pupil justify a demand for special schools for the mental, the physical and the moral defectives. The financial basis of medical inspection must be thought of. Where expense prevents a complete investigation, the work may best begin in the kindergarten and the primary grades. This plan will include practically all children under 10 years of age, and it is among these that the chief danger exists. This applies especially to the kindergarten in which, by virtue of different processes, children are brought into close contact with each other, and use in common a large number of objects liable to become infected. Comparison of the health reports of the cities now practicing inspection shows that an average of about 1000 pupils and three school houses is the capacity for work of each inspector. To be thorough, the work should include charity schools and day nurseries, quite as much as the public and parochial schools. Boston's annual pay to each medical inspector is \$200; that of New York \$300; making the total cost to New York \$45,000 per annum, irrespective of report blanks, office work and incidentals. In connection with this outlay, however, it must be remembered that the incident control over contagion causes a constant decrease in the work of the district medical inspector. The school work may thus in time become a paying investment. Coming next to the sanitary and hygienic side of the subject, the control that will be obtained over contagious diseases will redound to the credit of health boards and repay the community for all that it may cost. It has been estimated by one physician that 70 per cent. of epidemics might be prevented by inspection. There are many diseases upon which the law requires no report, parasitic diseases of the head, contagious diseases of the eyes, follicular tonsillitis, oral and respiratory diseases, and further mumps, whooping cough, measles, consumption and chicken-pox. Medical inspection will detect a large number of these. While the main purpose of inspection is the preservation of life, yet the community has a right to demand the best possible protection against the spread of the above named diseases and the consequent interruption of the school life of the child. In a very large number of cases the mildness of the disease or ignorance has prevented its recognition, etc.; the child nevertheless was in a condition to spread contagion. To quote Dr. S. H. Durgin, the Boston pioneer in the work, a child with an unrecognized case of diphtheria, not attracting attention, may attach infective matter to the desk, chair, books, slate, pencil, penholder, sponge, drinking cup, door knob, window sill, banister, wainscoting, or to anything which he may handle or touch after using his fingers about his mouth. The fact that these things may become

infected with diphtheria in this way has been conclusively shown in the laboratory by Prof. Ernest. This statement would seem to substantiate a plea for simple instructions and facilities for disinfecting purposes in the schools. The far-reaching effects of inspection can hardly be over-estimated. In Chicago, 744 individual cases of diphtheria brought to light 2619 cases at home, and 231 cases of scarlet fever disclosed 745 cases at home. Inspection should begin in the old school houses, as the number of sick children from these is greater than from the new buildings. If the School Inspector is alive to the possibilities of his work, full information may be incidentally gained as to defective conditions of school life and particular defects from time to time will be brought to the attention of the authorities. It will suffice to enumerate the conditions to which attention should be directed: Overcrowding, defective heating, plumbing and ventilation, dark basements, insufficient and uncleanly sanitariums, seating and school furniture, recess periods, overstudy and grading of pupils.

The medical profession quite generally, through the journals, have suggested or endorsed the movement for school inspection, and wherever established, the boards of education have co-operated in the work. After two years and a half of test, Boston reported the plan constantly growing in favor with the medical profession, among the teachers, and in the community at large. When organizing the work in New York, the Board of Health took the wise step of giving a few explanatory lectures to the school inspectors. It is hoped that a movement to institute the work throughout the State may result from this presentation of the proven value.

Discussion followed by Prof. W. W. KEEN of Philadelphia, who spoke from the sanitary standpoint.

He said that the State owed two duties to its children: That they should have a good common school education and that, as far as was possible, their health should not be endangered in school. In order to attain the former, compulsory school attendance had been provided by law. We had no right, however, to force children to go to school unless we protected them from infection of some of the most loathsome and deadly diseases. Compulsory vaccination provided against smallpox, but against diphtheria, scarlet fever and a large number of less deadly diseases no provision was made, unless there was a medical inspection of schools. Any child, therefore, was liable to be brought in contact with such diseases without any possibility of escape. It might be objected that these children could not be very sick if they were able to go to school. To this he replied, that at the beginning of many such disorders, and at the end, before health was completely reestablished, such children would be perfectly able to go to school; nor must it be supposed for a moment that only the serious type of cases was dangerous. A very mild case of scarlet fever in one child could easily give a fatal attack to another. An attack of diphtheria so slight as not to keep the child at home, much less in bed, might breed in the throat of another child the severest form of the disease.

Most of the epidemic diseases which are contagious arise in childhood. It is therefore particularly important that children of school age should be protected from them. The only way at present of having them protected is through reports to the board of health. But this does not meet the case entirely. There are a large number of diseases that physicians are not required to report, such as measles, whooping cough, chicken pox and the like, and a very considerable proportion of children attacked with these diseases succumb to them. The death rate in measles varies from only 2 or 3 per cent. up to 20 per cent. in severe epidemics. In 1880, 11,102 children died of whooping cough in the United States. Besides this, very many of the dangerous diseases which ought to be reported, are not reported because of the very mildness of the cases, when parents do not think it needful to call in a physician, and in others from the ignorance or wilful neglect of the parents, who endanger not only the lives of their own children but those of other people by not securing medical aid. The rich send for the doctor in the slightest illness. The poor often, from motives of economy, delay till they have to seek medical advice. Inspection of schools remedies most of these sources of mischief.

The figures given in the paper were very striking: In Chicago, in 744 cases of diphtheria among children at school, when the absence list was consulted and all families of absent pupils visited, it was found that 2619 cases of diphtheria existed at home, which would not have been revealed but for the school investigation; and similarly, 221 cases of scarlet fever in school children revealed 745 home cases. These home cases of diphtheria and scarlet fever were not only a danger to the school children, but to the entire neighborhood in which they existed.

Dr. S. D. RISLEY of Philadelphia The systematic medical

inspection of our schools, not only as regards the hygiene of the school house, but the examination of the individual pupils for the purpose of excluding contagious and infectious disease must commend itself to the judgment of every thoughtful citizen of our great commonwealth. At first sight, the problem of school inspection seems not only wise and necessary, but its execution very simple. When carefully considered, however, in all its phases, it grows in complexity, and difficulties at first unsuspected are confronted.

The primary purpose of school inspection is to exclude temporarily all children affected with forms of disease which may be communicated to others. It is unquestionably true that a cursory inspection of the throats of the children would exclude a large group of infectious diseases, either in their incipency, or when present in mild form and their real nature not suspected by the pupil or his parents. Systematic examination of this kind with carefully preserved records would soon prove of great scientific value as showing the possibility of warding off epidemics of measles, whooping cough, scarlet fever and diphtheria.

A careful study of the problem of individual inspection of schools leads us much farther afield than the simple exclusion of infectious and contagious disease. It is reasonable to expect that some degree of physical deterioration will result from depriving children of the freedom of the nursery and playground and subjecting them to the confinement and tasks of the school room; but observation has shown that a considerable percentage of those who enter upon the educational process in apparently good health soon manifest impaired general vigor, acquire distorted spines and develop near-sightedness. It is plainly the duty of those in authority to prevent these misfortunes as far as possible. It may not be generally known that modern school hygiene has grown to its present state of advancement through the individual examination of children for the purpose of discovering the cause of the steady increase in the percentage of near-sightedness as they advance in their educational process. It was at first supposed that this increase was due to bad hygienic environments. Attention was then directed to the quantity, quality and direction of the light in the school room, and to the proper relation between desks and seats. This led to a most elaborate study of the mechanics of sitting, and to extensive measurements of the different parts of the body in order to determine the suitable relation between the height of desk and seat. The print in the text-books, the script used in writing, and the position assumed by the pupil were all subjected to the most careful scrutiny. These elaborate studies in different parts of the world, by many observers, led to great reforms in school house architecture and in the furnishings of the school room, while the examinations of the children's eyes served not only to verify the fact of the steady increase in the percentage of near-sightedness, but demonstrated the relation between that and disease of the membranes of the eye. It was reserved for observations made in the Philadelphia schools to demonstrate that the inflammation upon which the near-sightedness depended was due to the presence of certain congenital defects in the eyeball, which necessitated a constant strain upon the organ of vision during school work; that therefore no child should be admitted to enter upon his school life until the eyes had been examined, when if one of these congenital defects were discovered, he could be sent back to his parents with the advice to have the defect corrected before admitting the child to the school room.

This was a distinct advance in school hygiene, the importance of which can not be overestimated, and was the direct outgrowth of individual inspection of the school children's eyes. It is altogether probable that were systematic inspection adopted in other lines we would see equally important advances made in the science of school hygiene. Most parents in seeking to enter a child at either our public or private schools have considered only the fact that a suitable age has been reached, no thought being given to any other requirement. That the child is in poor health, that it may have defective vision, impaired hearing, or may be mentally defective, are questions that have never for an instant been considered. The only thought is that the child is old enough to go to school. The point in contention in these remarks is that it is the duty, not so much of the health authorities, as of our school boards to subject all new pupils to a rigid individual inspection, as to the condition of their general health, the sharpness of vision, acuity of hearing, and their probable mental condition. At the beginning of each school year all of the former pupils should be re-examined. As regards the general health the requirements of the school board might be met by a certificate of good health from the family physician. This would be in the interest of both child and school. It is idle to expect a sickly

child to bear safely the same burden of toil and anxiety which is placed upon the shoulders of his healthy companions. While in some cases it might be wise to exclude the feeble child from school until in better health, there is a large group of physically weak or otherwise defective children, for whom special provision should be made in the required curriculum. Individual inspection should detect these cases and place them in the provisional class for which they are fitted. In it would be placed many children with defective eyes or ears, and with impaired general health. Their progress in school would be steady, but not so rapid as that required from their more fortunate fellows.

As it is at present certainly in our public schools, it is too often a survival of the fittest, the weak and unfortunate being compelled to drop out of the race. The individual inspection should cover, therefore, not only infective disease but search for impaired general and special functions, especially of the eyes and ears. Under no circumstances should any child with purulent discharge from the ears, or inflamed eyes, be admitted until subjected to expert examination; or if the vision is found defective, or the hearing impaired, they should be sent home with a note explaining to the parents how these defects must handicap them in their work at school, and urging them to seek professional advice. For this examination of the eyes, expert skill is not required. It is a simple matter to determine whether each child enjoys a normal acuity of vision or not. This procedure is not the best that can be devised but it meets the practical requirement of the case, and for many reasons is probably the only feasible plan. It would cost but little, and need not awaken the opposition of the parents or the family physician, both of whom are apt to be sensitive about any interference with their prerogatives. As regards the mentally defective, every educator must soon learn that these are not to be found only in the institutions for the feeble-minded. Medical or expert inspection on these lines is an exceedingly difficult and delicate problem, but nevertheless important. Mental defect declares itself to expert observation in many ways. Not only in dulness with books do we detect mental feebleness, but in bad habits, bad temper, incorrigibility, cruelty to playmates, moral obliquity, or even moral imbecility are often signs of hopeless congenital mental defect which should exclude the unfortunate individual from association with normal children, upon whom their influence is always deplorable, and their presence often dangerous. It is true that in some degree these signs are, many of them, the evidence simply of a defective home training, but it is equally true that many boys or girls who are regarded by their parents and teachers as simply bad, are hopeless defectives, and should be excluded from our schools and sent to institutions designed as training schools or asylums for the defective. Such children are often fine appearing, cunning and bright, and the teacher naturally supposes that they could learn if they would, but find to his disappointment that they add only to their store of craftiness. It is from such that our criminal classes are largely recruited. While still in school, the incorrigible pupil should instead of punishment be subjected to expert examination, and their parents or guardians frankly advised of their duty, provided the child is shown to be a member of this unfortunate class. The far reaching importance of this, in that it places these defectives under State control, will occur to the thoughtful.

While such inspection as has been suggested would unquestionably be of great value to the school children and to the community, great care must be exercised in the method of their adoption and the manner in which the inspection is made. School boards and boards of health are important institutions, but they must not be permitted to invade the domain of private rights, nor should they permit themselves to be drawn beyond their legitimate and proper functions by the specious pleas made not so much in the interest of public health as for the gratification of private ambition, or a desire for publicity. Little by little, almost unnoticed dangerous and arbitrary encroachments may be made by such excellently disposed gentlemen as compose our Board of Health, until we find ourselves on the border of State or municipal socialism. That it is proper that many things should unhesitatingly be surrendered to the State is set forth in the foregoing remarks, but we should be cautious as to the method of the surrender.

Dr. J. M. TAYLOR of Philadelphia said It is not expected that the teacher will become an expert in differentiating the forms of defective children, nor, in the strict sense of the term, be able to pick out or label the kinds of defects. That is entirely the duty of a physician and can only be done by one of sufficient clinical experience. Once the child has come under suspicion and been separated from the others the physician can do this thing. Then, if he finds himself unable to exactly differentiate, again an expert should be called in. The

kinds of children which will show defects are many, and some of these defects may be only temporary and yet the deficiency or disability be so marked as to render the child unfit for association with the others so far as competitive work in the same lines and to the same degree is concerned. Many children who present themselves in a school for the first time are in a condition of lowered intelligence from the simple cause of malnutrition, living a life of poverty or other defective hygiene. They present a condition of insufficient nourishment, anemia, and are weakened in many or all organs. They may have been subject to household demands, have been made to labor and are in that condition of fatigued state which Professor Schiedt has so admirably portrayed. They may have just recovered from illness, or may be in a condition of chronic disability from many states which should be recognized and treated by a physician. Often these children will be restored by a few days' rest in bed or a period of hospital care to the average of intelligence and alertness. They can then rank as an average child. Another class of disability, the result of defects in various organs, as the eye, have been alluded to by Dr. Risley: the ear will be spoken of by Dr. Randall, and a number of conditions which the medical inspector should promptly classify and suggest means for relief. A third class of defectives are so by reason of brain insufficiency. These may have been subjected to conditions not likely to develop the brain. Such may be improved in varying degrees. Some may require a special line of teaching. As a subdivision of this class mental states have been warped to one-sidedness. There may be quick observation, deep cunning, many of the qualities which enable the child to go along well enough in the ordinary walks of life, but not enough to progress along the lines of ordinary education as offered in the public school. They may be defective in powers of observation, slow in mental processes, with a fair share of symmetric activity which gives, if properly trained, sooner or later, a good quality of judgment, but only developed in lower lines of mental activity suited to their capacity. Such soon reach their limit of education. Another class will show morbid impulses, restlessness and tendency to do things which the routine of the school can not allow; yet if these were placed where they could get a form of education suited to their needs, they might be made more or less useful citizens. Finally, there is a class of mental defects which are inherently bad with distinctly evil tendencies, dangerous to mingle with other children, who ought to be separated and yet well deserve the most careful education to make them useful and less objectionable members of society.

All these classifications may vary from time to time in the same individual and a child who today or at the end of a certain year has made a fair measure of progress will need to be treated or educated in a different way the following year to bring out the best that is in him. Medical inspection will enable all these points to be elaborated and the work now being done in certain large cities in the maintenance of special schools for the mentally deficient is magnificent work, to weed out from ordinary children those who require separate training, and also for the good of the children who are thus freed from these objectionable elements. Again, those separated, classified and properly trained will do great things, but if left to blunder along with the others would fail to be other than a burden to society. No teacher can be expected to be an expert, it must be a physician. The physician must exercise his faculties for months, even years. The study of children is exceedingly important, demanding the highest qualities of heart, brain and observation. It is to be regretted that most people believe children are easily understood. The inspection proposed will serve as a great economy of lives and capital. To be able to pick out promptly and subject to proper treatment those instances of contagious diseases, etc., will not only save many lives, but prevent spread of disease and enable many to grow up and take their places as bread-winners. Again, by the separation of these cases it will limit such diseases so considerably that fewer inspectors will be needed.

Dr. B. ALEX. RANDALL of Philadelphia wished to lay stress upon the aspects of the matter with which his experience had made him familiar, the examination of the eyes, ears and nose. Now that the school life is made compulsory, it is doubly incumbent upon the authorities to protect the children from the consequences of their own ill as well as from those communicable by their companions. The hygiene of the scholars demands that examinations be made as to their physical as well as their mental fitness for the tasks assigned them; for good school hygiene only means that the surroundings should be innocuous to normal pupils. But study shows that few children even approach a true normal and that a considerable proportion are so far short of it as to take serious harm from their

school work. Disqualifying defects should be discovered at the beginning, when they are more likely to be remediable, than later, and threatening contagion noted and guarded against. This means a vast amount of work if well done, and if not is of little avail, or even leads to false security. The mere presence of a set of test letters in the schoolroom will show many that their sight is not up to the normal standard; but in this as in the other directions skilled study is needful to bring more than a fraction of the unpleasant truths to light. Any intelligent person can make many eye tests accurately, unless he insists on varying the methods of examination; in some railroads every new employe is required to show to the non-medical examiner his possession of adequate sight and hearing. But to learn that the eyes and ears are likely to remain good requires the expert medical examiner. Much work done in this direction has been inadequate, yet it may have had much value to the individual examined. My contention is that it is almost as easy to do it thoroughly as to slur it in slipshod manner. Examination as thorough as most specialists make in their offices can be made of the eyes, ears and of the nose and throat in about five minutes per pupil and subdivision of labor may reduce this. Few instruments are required that could frighten a child or in any flaw of sterilization be able to convey infection. Usually the school can afford a fitting room for the work and the individual need lose but ten minutes or less from his routine duties. There is room for objection by silly or contentious parents or pupils, as with regard to vaccination or any other sanitary invasions of individual liberty, but large schools in Philadelphia had the matter carried out annually for years without friction. The main difficulty will be in securing efficient examiners without excessive expense. Considerable experience and technical skill are requisite and those having such are generally too busy to care for the small honorarium likely to be paid. Yet if the work be carefully subdivided it is probable that competent men can be induced to undertake limited amounts of it, principally on the ground of its scientific interest and its value to the public, as they now serve in unpaid hospital positions. Many will not continue it after a year or two of its drudgery; yet the system will grow and perfect itself if carefully supervised and many points now set down by skeptics as impracticable will show themselves not only possible but really essential, and we will later wonder how we could expect to get on without such inspection of our schools.

(To be continued.)

Chicago Gynecological Society.

Regular Meeting April 15, 1898.

The President, Dr. HENRY P. NEWMAN, in the chair.
Dr. W. S. CHRISTOPHER spoke on the

NATURE AND MANAGEMENT OF PUBERTY.

He presented for consideration the proposition that puberty is a period during which force is recognized in a peculiar manner for subsequent use in a special manner. That the factors which interfere with the accumulation and latentization of this force interfere with the subsequent act of reproduction in all its phases, and that those factors, on the other hand, which favor the latentization and accumulation of this force, favor the subsequent factors of reproduction. Reference was made to the scientific contributions of Herbert Spencer, who has shown the antagonism between expenditure and genesis, as well as the antagonism between low nutrition and genesis. The speaker said the proposition that low nutrition and high activity are antagonistic to reproduction or genesis, and the converse, that low expenditure of force and high nutrition are favorable to genesis, is tolerably well established. Examples were given. He said it was unquestionably true that the expenditure of nerve force or physical activity, which goes on in the life of the individual during the generative formative period, was certainly greater than it was fifty years ago. There was no doubt in his mind but what the enormous degree of labor thrown upon girls about the time when they were passing through the period of puberty was greater than it was a generation ago. It was a common thing for him to find high school girls failing in their work, and it became necessary to take them from school or diminish their work very materially in order that they might develop properly. It was about the time they entered the high school, or before, that these changes began to show themselves. He cited the case of a girl, 12 years of age, who last October was taken sick with some trilling disorder. On questioning her, he found that she was constantly tired at the end of each school day, and extremely so at the end of each school week. She was removed from school, with

the result that from October until the present time she had gained considerably in weight, strength and personal appearance, and instead of being a fagged out, miserable mortal, she was now a blooming girl, fully up to her age and all that would be required of her in the future.

Dr. JOHN C. COOK thought that physicians were too careless in the general management of boys and girls during the period of puberty. He said: Girls particularly should be taught to stand up straight and to inflate the lungs in such a manner that the nutrition will be greatly increased by so doing.

Dr. BAYARD HOLMES read a paper entitled

HOW TO RECONCILE MODERN EDUCATIONAL METHODS WITH THE DEMANDS OF HEALTH.

He said the growth of the American girl into womanhood generally began at the end of the eleventh year, or some time during the twelfth year, or at the beginning of the thirteenth year, and it progressed with very great rapidity for a year and a half or two years. The law of growth in the human body was one which had not been always considered in relation to the development of girls. The energies of the body rose and fell in each individual with a certain rhythm. Each swell of physical growth was designed to bring about certain morphologic and functional conditions, and when those conditions were not secured at the time nature was accustomed to bring them about, there was absolutely no possibility of their completion and perfection in subsequent years. The maturity of the sexual apparatus and its function in the girl must be secured in that stage of development known as puberty. It was of all the periods of growth of the woman the most important for her future health. Therefore, it was the one above all others which should be considered in the education and training of the girl. All the intelligence and care that it was possible for teachers and physicians to bestow upon her should be given at that time. Not only motherhood and subsequent health, but sanity and life-long happiness were dependent upon the perfection of pubescent growth and function. It did not seem unreasonable, therefore, that the customs and prejudices of the time should be entirely laid aside in considering the proper education of the girl in and before pubescence. In the first place, it was to be recognized as a fact that our present educational methods, both at home and in school, were productive of imperfect women. The ever-increasing number of cases of breaking down, nervous prostration, dysmenorrhea, sterility and hysteric insanity, both among the highly educated and those who left school and entered "gainful occupations" early in life, was recognized by all.

As our public city schools, and most private schools, were now arranged, the boys and girls were educated together, having the same exercises, the same lessons, the same requirements and the same female teachers. This seemed to him the beginning of disasters. The girls should be at that time separated from the boys, the boys going under the care of men and masculine discipline, and the girls remaining in the care of women of experience and education, who would consider the fact that that increasing sensibility and excitability was a part of the pubescent development, and should not be too strongly encouraged.

In the girls' school in the city the occupations should be less and less desk or book study, and more and more the exercise of the hand and eye and body. The ideal school for the girl would make the schoolroom into a house or home in which all the domestic duties would be systematically taught by actual exercise. The schoolroom for the twelve year old girl would have many stoves for the preparation of at least one meal a day; it would have several bedrooms for the exercise of the art of decorating and preparing the sleeping room. Those domestic services would be performed, not for the purpose of educating good servant girls or skilful housewives, but for the purpose of developing the young girl physically and mentally. The cooking would become the basis of the study of physics and chemistry, as well as incidentally the exercise of English grammar and mathematics.

The preparation of the furniture for the sitting rooms and sleeping rooms would be done with the same educational idea. The sewing and the weaving would be made the basis of the study of the history of culture and civilization, and also an exercise of the lost domestic arts. Those school exercises would be most helpful in developing the body of the young girl by interrupted exercises of great variety and they would develop her mind by giving play to the imagination and by contact with real things, methods much neglected in our present educational system. The girl would become a handy, effective, self reliant woman. It was possible that she would have no less skill in English composition than was secured by the present method of encasing the girl in a mahogany and cast-iron

seat for six hours a day and cramming her by means of the memorizing and recitation method. When pubescence had been established and the girl had become a woman, it was possible that she might be able to withstand the trials and the burdens of our medieval and pedantic educational system and take her place in the last years of the high school or the beginning of the college course side by side with the men.

Women must become productive and independent members of society. Less than one-third of the women of the country were brought up in cities. The surroundings of the country girl were quite different from those of the city girl, and yet they were much influenced by the customs and habits of the great aggregations of people from whom civilization takes its name and inspirations. The country girls were trained as nearly as possible as the city girls were. They were taught to read, write, spell, figure, write compositions and read French and Latin, and despise all sorts of domestic or manual labor.

Dr. W. O. KROHN followed with remarks on the same subject. He mentioned a series of experiments and showed charts giving the relative lung capacity in boys and girls. He said modern educators were seeking to re adjust the course of study to fit the child both as regards physical facts and mental facts. In the matter of exercises they were managed according to growth periods, and there was no period more critical, and one that required so much close observation as the period of pubescence in both the boy and the girl. He exhibited a chart which represented the physical exercises most beneficial at different ages. Exercises at the period of from 9 to 14 years were classed under three heads, viz.: 1. Exercises that bring about incitement to, and the formation of growth. 2. Those which contribute to the acquirement of a graceful carriage or nice walk. It was during this time that the muscles of co-ordination passed through their particular phase of development, and this development could not so advantageously take place at any other period, and those physical exercises which conduce to grace and beauty and ease of posture must be given to the child at this stage of his or her career, in order to reap the advantages to be gained from such exercises. 3. We must have at this period exercises that conduce to practice and to skill. Forbidden exercises were those that conducted to straining of the muscles, and should be avoided because of impending molecular changes at this period. Exercises of endurance should be stopped when fatigue manifests itself. Long continued piano-practicing on the part of the girl at this stage was harmful, if carried beyond the point of endurance.

He said our modern methods of education must be re-adjusted to fit the child rather than the notions of any school board or superintendent, apart from his knowledge of children and ability to frame a logically trimmed, neat, pretty course of study. Teachers were beginning to realize more and more the important point that education must not be acquired at the expense of health.

Dr. ALBERT GOLDSPOHN had in numerous instances ordered girls, between 6 to 13 and 15 years of age, to remain a year out of school, and had observed marked beneficial results from such advice, as for instance, the cessation of excessive menstruation in those who were already menstruating; the cessation of persistent headaches, nosebleed, vertigo and dyspeptic phenomena, and occasionally of persistent neuralgias. He recommended exercise in the open air and the avoidance of sedentary occupations.

Dr. SARAH HACKETT STEVENSON said experience and observation had taught her that it was not the educated women who were the invalids. Before she had undertaken a trip abroad she was told that nearly all of the illness was among American women on account of excessive mental work. During her European trip she saw the dispensaries filled with women who had never crossed the threshold of a schoolhouse, consequently the cause of disease could not be reasonably ascribed to the education of women. The fact of a girl being in school and subjected to a certain amount of discipline at the period of puberty was rather beneficial than otherwise.

Dr. ERRANT believes it is good for a girl to be educated; at the same time the mental strain at the period of puberty, incidental to competition with boys in school, had its injurious effects.

Dr. FENTON B. TURCK spoke of the importance of having a system of dietetics suitable for age, time and conditions of children. The question of malnutrition in school children was the first to confront both medical men and teachers.

Dr. FRANK S. CHURCHILL dwelt briefly upon the importance of not overburdening the child mentally or over-straining its nervous system at the age of puberty at the expense of the physical body. It was of the utmost importance for physicians to encourage outdoor exercises and sports among girls and boys, and get them into the open air as much as possible. He said

that President Eliot of Harvard University had remarked that "the future of the American public depends upon getting the children of our large cities out into the country for as long a time as possible during the summer." This was easy of accomplishment among the children of well-to-do people, but unfortunately it was a much more difficult problem among the children of the poor.

Dr. C. S. BACON said in the management of puberty the first problem was to carry the child, particularly the girl, through this critical stage in such a manner that she shall go forth strong and sound; consequently there were three questions for consideration, nourishment, nutrition and exercise. If it was the object of the boy to become an editor, or the school girl to become an editress, it necessarily followed that her training should be to a great extent the same as that of the boy in order to meet him in competition. Our schools, as now constituted, were, he thought, conducted on the false principle that the training of both sexes should be to the same end. This had already led to fierce competition between the sexes and professions, which was ruinous to families, and would in time be more and more injurious to the female members of the race.

Dr. FRANCES DICKINSON mentioned cases to show that the ciliary muscle does its work the same when the child is in school as when it is out of school.

Dr. FRANK A. STAHL thought the school boy, by means of calisthenics, was fairly well developed physically. When, however, such a boy was put to work, in a short time the red cheeks and rotundity of form disappeared and the natural tendency to be active had given place to a certain amount of lassitude. Physical training and the development of the mental faculties should go hand in hand.

Dr. JOHN T. BINKLEY, JR., stated that his observations did not agree with those of Dr. Stevenson, in that he had found young women who were well educated, as school teachers, the least fit to undertake the work of nursing or any work which entailed much physical exertion. He recalled several instances among the school teachers who had undertaken nursing and abandoned it. He mentioned similar experiences in other walks of life. He places considerable importance on environment in the development of both sexes. The diet of children among the wealthy was carefully looked into and carefully prepared. The social demands upon wealthy parents were so great that in many instances the mothers could not take proper care of their daughters.

Dr. HENRY P. NEWMAN regretted that the obstetric and gynecologic aspects of the subject had not been elaborated more fully. The conditions seen by the gynecologist as a result of improper education or carelessness during the period of puberty were appalling. Attention should be called to them repeatedly, and when women and the public become better educated these conditions will be corrected. It was not intended to suppress education along this line, but to broaden it and thereby assist in eliminating those elements which will tend to greater preservation of the race.

Dr. HOLMES, in closing, said that one of the principal aims of his paper was to call attention to what could be done to make the school correspond with the requirements of the physical growth of the girl. He had nothing to say relative to the physical growth of the boy.

Dr. KROHN remarked that the object and aim of the American school were to develop the best type of manhood and womanhood and the best citizen, physically, mentally and morally.

French Congress of Internal Medicine.

Tuberculosis, mixed infections and organ therapeutics were the subjects of the day. Revilliod classified certain diseases as tuberculogenic: grippe, diphtheria, syphilis, puerperal fever and alcoholism. On the other hand, he stated that there are a number of diseases which absolutely veto the tuberculous infection; some are constitutional, such as arthritis in its multiple manifestations; others, while possibly favoring the tuberculous invasion, proceed to alter the soil until the infection spontaneously dies out. Evidences of this are seen in the stigmata of spontaneously healed tuberculosis found at one-fourth of all the necropsies. This latter class includes erysipelas, epilepsy, local tuberculosis, scarlet fever, typhoid fever (out of 1614 tuberculous patients in his service only 49 had typhoid antecedents, and most of these recovered from the tuberculosis), and diseases affecting the lung tissue; emphysema, sclerosis, putrid bronchitis, pulmonary gangrene, also pleurisy and pneumothorax, which, occurring even in advanced tuberculosis, may effect such a change in the lung tissue as to stamp out the tuberculous infection. "This antagonism between the lesions should lead to research to discover the anti-

toxin that exists from the beginning in certain organisms and develops spontaneously in others." Bosc urged the parasitic nature of cancer and that all ulcerated cancers should be considered contagious, suggesting that domestic animals and insects may convey the contagion, especially in damp, wooded districts. Vedel reported that he had succeeded in inoculating a number of small animals with malignant tumors from man. Arloing has been applying sero-diagnosis to tuberculosis and found that the bacilli were agglutinated 94 times in 100 cases of pulmonary and 91 times in 100 of surgical tuberculosis: 34 in 100 cases of different affections and 22 times in 100 apparently healthy persons. Revilliod confirmed the great benefits derived from his siphon treatment of purulent pleurisy, which constantly aspirates the air, expands the lung by its negative pressure, renders resection of the ribs unnecessary and cures even so-called incurable pleurisies. Arloing stated that the diphtheria toxin and antitoxin both affect the respiration and circulation in the same way, increasing the number of respirations and pulsations and diminishing the arterial pressure. It follows that if the serum is introduced into an organism already strongly affected by the toxin, the effect is cumulative and hastens the fatal termination. Charrin reported that the urine decreases in amount under the influence of the toxin, while the serum increases the renal secretion. Pitres called attention to the fact that the displacement of the heart in pleural effusions is a providential process to protect it and keep it in a normal atmospheric pressure so that the valves can work properly. Hence the danger of bilateral effusions, in which this process is impossible. Gallard considers pyo- and hydro-pneumothorax in phthisis a *noli me tangere*. Courmont reported the case of a woman with Addison's disease transplanted with the suprarenal gland from a dog, causing hyperthermia, collapse and death in twenty-four hours. Two other similar cases have been reported, and they emphasize the danger of transferring to man the conclusions of successful experiments on animals. The result may possibly depend upon the fact that the gland was derived from another species.

In regard to mixed infections, Vidal asserted that each infection impresses its peculiarities upon the serum. He has obtained a whole series of agglutinative reactions in a single animal and found them reproduced in its young. "Mixed infections are probably of greater importance in diphtheria than in any other disease." Bacteriologic examination of vaccine lymph discloses a varied flora which tends to disappear as the lymph grows older. The preponderant rôle of mixed or secondary infections in case of influenza is familiar to all practitioners. He noted that the streptococcus passes most readily from mother to fetus, as it is carried by the lymphatic and sanguine circulation. The failure of antistreptococcus serum was ascribed to the number of varieties of streptococci and the fact that it is only effective against the identical variety from which it is derived. This renders it impossible to guarantee its effect for general use. Meyer announced that he has treated over three hundred cases of non-diphtheritic inflammation of the pharynx with gargles of sodium salicylate, 6 to 8 grams in 120 grams water, which he considers the best medication for the purpose; the pain, constriction, etc., are relieved at once. Chambard-Hénon reported three patients with biliary lithiasis, whose attacks ceased with the external application of methyl salicylate. Some experiments were related terminating with fatal meningo-myelitis caused by the action of the Roentgen rays on the spinal column. A village epidemic of typhoid fever was traced to the dejecta of a typhoid patient thrown into the street and mixed with the dust. Eighteen of the thirty four cases were children who played in the street. Sweeping and sprinkling the street ended the epidemic. After reviewing the history of organ therapeutics, including the recent theory that the histones substances existing normally in the organism can be introduced to reinforce its means of defense against infection, and mentioning the increased power of resistance conferred on the dog and guinea pig by injections of extract of leeches, liver, dog's intestines and calf's thymus, Mossé reviewed the present status of thyroid medication, the most important application of organ therapeutics to date, observing that opinions are divided as to the nature of the toxic substances which accumulate in the organism after the suppression of the thyroid function, and also as to whether the extract acts as a stimulant of the nervous system or as a neutralizer of the toxic products engendered by fatigued muscles, etc. The effects of the secretion of the thyroid gland do not seem to be due to a single active principle, as two have already been discovered: Baumann's iodothyron which has proved effective in treating trophic disturbances and the chronic toxemia of hypothyroidism, and Frankel's thyreo-antitoxin, which has not yet been applied to therapeutics, although experimentally it seems to neutralize acute toxic accidents (tetanus, convulsions).

It is apparently established now that the thyroid gland holds the iodine brought into the system in the food, preventing injury to the nerve-centers from this metalloid, while at the same time it elaborates the iodized peptone discovered by Baumann. Mossé prefers ingestion of the fresh gland and asserts that the results of this direct opotherapy are excellent in the spontaneous myxedema of adults and congenital infantile myxedema, also in endemic cretinism. Cystic, vascular and cancerous goiters are not affected by it, but the results have been very favorable in fleshy goiters, especially in young subjects and in an early stage. Improvement is rapid if obtained at all. Thyroid treatment is usually injurious in classic Basedow's disease, but is often very useful in "basedowified goiters." This treatment also seems to be indicated in dysthyroidism with or without goiter and perversion of the cerebral faculties. The results in trophic disturbances, infantilism, arrested growth, etc., justify further trials, but in rachitis they are contradictory. He also cited contradictory results in obesity and diabetes. Doses should be small and at long intervals: the condition of the liver and kidneys carefully noted, they may not be able to stand abrupt "demyxedemisation." A neuropathic temperament, arthritism, obesity, also indicate caution; the urine should be periodically examined and medication suspended at the first sign of intolerance. Improvement has been noted in some gynecic troubles, and he urged further trials and research in this line, which may prove important as a means of administering already animalized iodine. Cereville attributes an important rôle to the chemic substances contained in the juices of the glands, iodine, phosphorus, iron, assuming that these natural combinations have more powerful physiologic properties than ordinary chemic compounds. Possibly the glands elaborate ferments which affect the metabolism of the cell through the blood. Gilbert and Carnot reviewed the technique of preparing organ extracts, giving the preference to an aqueous extract. The organ is mashed and macerated in water, filtered and partially concentrated in a vacuum or with gentle heat. Thus prepared the extract represents 6 to 7 per cent. of the fresh organ. Ovarian extracts, "effective in troubles due to surgical castration, and useful in the disturbances consecutive to the menopause, do not seem to affect the troubles originating in genital affections." Extracts of the spleen, kidney, lungs, brain and pancreas, are still on trial, but extract of liver has already taken a high rank and proven "rich in experimental and therapeutic results." It has been successfully used in diseased conditions of the liver and in other affections comprehended in the term "hepatism." Its marked antitoxic and coagulating properties also render beneficial against certain symptoms. But it has proved most effective in arthritic affections, especially gout and diabetes mellitus. The sugar eliminated fell from 155 to 85 grams in one case; from 81 to 11 in another. Hemoptysis has also been arrested by injections of liver extract. They concluded by classifying the organs: 1, those that only act as vital process, and 2, those that transmit their properties to an extract. The kidneys, pancreas, marrow, etc., may belong to the first class, which would explain their failure in opotherapy, while the liver belongs to the second class. The action of the organ extracts also differs in another important respect: some reproduce *in vitro* the glandular action, such are the gastric, pancreatic and hepatic extracts, which are mostly diastases; others, active *in vivo*, are inactive *in vitro*; liver extract, for instance, does not transform sugar *in vitro*, but does *in vivo*, probably by stimulating the glycogenic function of the hepatic cell. The success of ovarian extract in chlorosis (17 cases), was reported by Etienne, and the cure of severe hemophilia with thyroid treatment by Combemale. Others announced very favorable results from the administration of lung juice. "It has demonstrated its efficacy as a heroic remedy for the general intoxication consecutive to pleuropulmonary septicemia, although its use must be long continued." The improvement obtained in ordinary tuberculosis is slight and transient. Lemoine confirmed his previous announcements in regard to the value of methylene blue in arresting pain in neuralgia, sciatica, etc., and reported several cases of diabetes and gonorrhea cured with it.

The German Congress of Surgery.

Berlin, April 13.

The principal incidents of this Congress seems to be its repudiation of gloves and of Calot's forcible reduction treatment of Pott's disease. If the hands are washed several times during an operation and rubber gloves worn to protect them in septic cases, that is generally considered sufficient, and Mikulicz' "full dress costume" of mouth mask, cap and lisle-thread gloves is not generally endorsed, and the gloves even considered bacteria absorbers by some.

He concedes that efforts to secure absolute asepsis are like trying to square the circle, and others claim that asepsis is not necessarily the absence of germs, as witness the aseptic course of wounds in mouths swarming with bacteria. Perthes exhibited flexible gloves made of silk tricot and rubber, and Friedreich, seamless gloves of thin natural rubber. Both bear steam sterilizing a number of times. Mikulicz controls the sterilization of bandages, etc., by having a strip of paper with the printed word "sterilized" pasted in the box, and stained with an iodine-potassium iodide solution until the printing becomes invisible. When the steam permeates the box sufficiently to fully sterilize the contents, it dissolves the stain and the printed word appears again. Another device is a small tube of brencatechin which is expelled at a certain temperature. He keeps his fingers sterile by painting the tips with tincture of iodine. Schloffer stated that the secretion of a wound is strongly bactericidal for five to six hours, even to artificially implanted pus cocci, but that this property is lost if the secretion accumulates and stagnates, when it favors the growth of bacteria. In regard to auto-absorption Noetzel stated that fifty anthrax bacilli inoculated subcutaneously killed the animals, while 1000 could be injected into a vein without fatal results. An important announcement was that pneumonia and bronchitis follow the use of local Schleich anesthesia in laparotomies as frequently as after general narcosis, although there is no vomiting (Gottstein, 233 applications). The Oberst method was endorsed, but the drawback of pain from the ligation of the member was noted and an easier method of arresting the circulation hoped for (*vide JOURNAL*, p. 496). Twenty cases of empyema successfully treated with the Schede thoracoplastic method were presented, but all were children. Perthes reported brilliant success with an ingenious aspirating contrivance resembling a Bunsen water-air pump which aspirates the pleural cavity and ensures the expansion of the lungs by its negative pressure. Three old and nine recent cases were completely healed in fifty-five days at farthest. Lenhartz also endorsed its efficacy from experience in one case. Karewski reported the case of a woman with empyema, tuberculous peripleuritis and a tuberculous focus in the lower lobe, completely cured by extensive resection of the thoracic wall, curettement and cauterization of the lung focus. He has performed eighteen extensive operations on the thorax including five with lung complications. No deformities resulted, even with children.

In regard to resection and extirpation of the stomach, Krönlein observed that Schlatter's patient was still doing well and had gained thirteen pounds since her stomach was removed. She eats and drinks the same as a normal person. He has had only two deaths in his last seventeen operations for cancer of the stomach, which he attributed to the use of ether and strict asepsis. Schuchardt exhibited a preparation from a patient of 58 years, whose stomach and duodenum had been almost completely removed on account of a large tumor. The remnant of each had grown, as evidenced by the increased production of hydrochloric acid, until a large blind sac had been formed, mostly of duodenum, and capable of holding 500 grams of liquids. Death was from pleuritis long after perfect recovery from operation. Czerny has found that many cases of cancer seem to retrogress like tuberculosis after a laparotomy. A number of patients with inoperable cancers (adhesions), gastro-enterostomized, have lived to two and one-half years. This operation for non malignant strictures produces fine results. His mortality has fallen from 45 to 16 per cent. in his total of 290 operations on the stomach. Mikulicz insisted on an earlier diagnosis of cancer of the stomach. Swelling of the supraclavicular glands is often the first symptom. It is necessary to extirpate all the avenues along which the cancer may spread and the glands toward the pancreas are the most difficult to locate, but it does no harm to open up the pancreas aseptically. The Billroth method can not be applied in extensive resections. Hahn mentioned that in his 141 gastro-enterostomies eight resections, all over 60 years of age had died, and he considers this age a counter indication for resection.

Bruns described the wounds inflicted by the "dum dum" bullets used by the English in India, already editorially condemned in the *JOURNAL*. He urged the Congress to call the attention of the authorities to this violation of the St. Petersburg convention. Kümmell presented some patients cured to date of lupus by means of the X-rays or concentrated light. Lewy Dorn protects the operator with the fluorescent screen against all the rays except those passing through the radiographed person, by enclosing the Roentgen tube in a lead box, with only one small opening for the passage of the rays. Walter also recommends placing the patient in a lead box, exposing only the part to be radiographed. This effect is

accomplished more easily with an adjustable board covered with lead. Most of the other communications presented have already been published and been reviewed in the *JOURNAL*. The Association has been presented with 50,000 marks, as a fund to send certain members to military campaigns in which Germany is not directly interested.

Chicago Academy of Medicine.

Regular Meeting, March 18, 1898.

(Concluded from page 1414.)

TUBERCULOSIS OF THE JOINTS.

Dr. JOHN RIDLON—More than one-half of all the work of the orthopedic surgeon does is in the treatment of tuberculosis of the joints. Tuberculosis may attack a joint either in the synovial membrane or in the bone. There is no evidence that it ever attacks a joint in the cartilage or in the ligaments. It is probably occasionally a primary infection. It is probably generally a secondary infection, secondary to tuberculosis in some of the glands, generally in the thoracic glands.

The positive symptoms of joint tuberculosis, when the disease is confined solely to the synovial membrane, and in those cases where traumatism has not been a predisposing cause, are those of swelling, thickening of the synovial membrane and simply a mechanical restriction of the extremes of motion of the joint. In bone tuberculosis, that is, when the disease begins in the bone ends and before the synovial membrane is involved, there is no swelling of the joint except in cases of traumatism. The diagnosis must depend upon the restriction of motion in every direction to a greater or less degree. If in one direction motion is normally free, the diagnosis of tuberculosis must be seriously doubted, and probably excluded. This restriction of motion is from involuntary spasm in those muscles that normally control the motion of the joint. This condition is always present. The next symptom, which is practically always present, is atrophy of those muscles that control the motion of the joint in question. I have never seen but one case in which there was not this muscular atrophy. There may or may not be pain. If there is pain it is usually a distant rather than a local pain. There is usually some deformity, especially if the tuberculosis affects the joints or bones of the spine or of the lower extremities. The deformity is usually in the direction of flexion in the hip, associated with abduction or adduction, and flexion at the knee with outward rotation and abduction, plantar flexion at the foot, adduction at the shoulder, flexion at the elbow, flexion at the wrist and flexion in the smaller joints of the toes and fingers. In the spine, the first deformity is usually a lateral bend followed by a posterior bend or angle. Tenderness may be found in bone tuberculosis when the joints are superficial. Local tenderness is not found in spine tuberculosis, inasmuch as a tubercular focus is found in the vertebral bodies in practically every case. Disability comes on early and is very persistent. These practically make up the symptoms of joint tuberculosis.

The complications of joint tuberculosis are abscess, and in some joints dislocation, and in spine disease in a few cases paraplegia from pressure upon the spinal cord.

Cases of joint tuberculosis, if left without treatment, go on to a certain degree of deformity and disability and then the vast majority of them go on slowly toward a complete recovery of the disease. The tubercular focus may be evacuated by the formation of an abscess. It may become encapsulated or it may become absorbed by healthy granulation tissues. From 8 to 30 per cent. of the cases that are not treated die. A good many die from general tubercular infection; a good many of those that die have tubercular meningitis. A few of them die from waxy liver and kidneys, where there has been prolonged suppuration and the presumption of septic infection. Cases that are treated by orthopedic measures show a smaller percentage of deaths. Probably not more than from 8 to 15 per cent. of them die when so treated. The vast majority die from general tuberculosis or tubercular meningitis; and a few also die from waxy liver and kidneys.

The principles of treatment of all tubercular joint diseases are few and simple. The joint must be held as nearly immobilized as possible by mechanical means. The weight of the superincumbent parts must be removed in cases of spine, diseased joints of the lower extremities, and the dragging weight of the limb in shoulder-joint and elbow-joint disease oftentimes must be removed. This embodies the entire principle of orthopedic or mechanical treatment. As to what means shall be used to effect this immobilization and thus relieve the patients of pressure, the surgeon in charge must decide and resort to that method which is most fitted for the joint, which

is best adapted to the patient, which will be best cared for by the family and which will cause the least criticism by the neighbors; for these cases must be treated for many years, and oftentimes you have to control the whole neighborhood as well as the individual joint.

The treatment of the complications will be as follows: As to the treatment of abscesses, there is a very decided difference of opinion between the orthopedic surgeon and the general surgeon. The majority of general surgeons believe that all tubercular abscesses in connection with joint tuberculosis should be opened at once and treated "surgically." The orthopedic surgeon believes that these tubercular abscesses should not be opened so long as they are simple tubercular abscesses, and should only be opened when they become septic; in other words, so long as the patient shows no septic symptoms the tubercular abscesses are left untouched unless they interfere by their position with the mechanical treatment of the joint. If the joint is thoroughly immobilized and protected from injury, possibly one-half of the tubercular abscesses will never proceed to spontaneous opening. They will become absorbed sooner or later and leave no evident result behind. They will give no unpleasant symptoms to the patient. The patient will never be aware of their existence from any illness, fever, loss of appetite, loss of weight or any ill feeling. When these abscesses approach the surface and become very thin the pressure becomes very great, from without, to open them, and most general practitioners will yield to that pressure and believe it is as well to prick an abscess wall if it is not more than one-sixteenth or thirty-second of an inch thick, instead of leaving it for a week or two or three weeks to break of its own accord. My experience has been that it makes a great difference which you do. If you leave them alone to break and to discharge of their own free will, without any pressure to evacuate the contents, the patient will rarely show septic symptoms, and by that I do not mean that I know the abscess cavity does not become septic. I simply know from clinical experience that the patient does not show septic symptoms, while in those that are freely incised, in the vast majority of cases, sooner or later the patient does show septic symptoms. When these abscesses cause septic symptoms before they have opened spontaneously they should be freely opened, they should be cleaned out and left open, and they should not be drained with a rubber drainage tube.

As to aspiration of tubercular abscesses, it is in my judgment a most absurd and ridiculous procedure. If the abscesses are aspirated early, while they are still in connection with tubercular bone, they will surely refill. If an attempt is made to aspirate them after the bone lesion has healed it will be found to be impossible, because the contents will have become clotted and curdled so that they can not be completely evacuated.

With regard to the injection of various substances, of which iodoform has been the chief one for the past five or ten years, the orthopedic surgeons are thoroughly in accord that it is a useless procedure, that no case is benefited by these injections, and that very many are made worse by this method of treatment.

As to the treatment of complications or dislocations in conjunction with tubercular joint disease, there have been one or two cases reported, I believe, where a dislocation has been reduced and a cure has resulted without a redislocation. Usually this can not be done, and the effort is not worth the while.

As to the paraplegic complication in Pott's disease, practically all of these cases fully recover from the paraplegia if the patient is kept in the recumbent position sufficiently long. At present it is fashionable to attempt to relieve the paraplegia quickly by forcibly straightening the spine under an anesthetic, and a few brilliant results have been had from this method of treatment, but as yet it is so young that we can not say positively as to what the ultimate result is to be.

There is one point that occurred to me when Dr. Paddock was speaking, and which I wish to refer to outside of my remarks, namely, it is my personal experience that all cases of tubercular joint disease grow worse during pregnancy; that if they have had tubercular joint disease from which they have recovered, they are not necessarily made worse by a later pregnancy. At any rate, the risk is not greater from later pregnancy than from any other weakening condition.

Another point occurred to me during Dr. Babcock's remarks with reference to lung tuberculosis. Most parents are curious to know whether their child who is suffering from joint tuberculosis is likely to die from consumption. Unless it dies from general tubercular infection during the active course of the tubercular bone disease, my experience is that such children are not likely to die from consumption. Indeed, they are less likely to die from consumption than other people.

THE PEDIATRIC ASPECT OF TUBERCULOSIS.

Dr. ROSA ENGELMANN—Infants and children constitute a large horde of the victims, and run the gamut of almost every form of this malady. Of some manifestations they are almost the exclusive subjects. I need but mention scrofulosis or chronic glandular tuberculosis, coxitis, Pott's disease, primary intestinal tuberculosis, tubercular meningitis, and even solitary tubercle of the brain, spinal cord and spleen.

The excessive mortality in children from this disease is appalling. Before the antitoxin era, the diphtheria ratio headed the list: now a 35 and 48 per cent. tubercular mortality takes precedence. The gastro-intestinal death-rate of infants receives the attention of health boards, but compare its yearly 3 per cent. rate with the above mentioned proportion of deaths. Burdon Sanderson says, "That one third of all the children that die in hospitals die from tuberculosis." Indeed, one-third of all deaths in early years are due to tuberculosis. Simonds states that 35 per cent., or over one-third of infantile mortality in the second year of life, is ascribable to tuberculosis. Hecker of Munich, in his statistics of 700 autopsies upon children, discovered 21 per cent. of latent tuberculosis, 1 per cent. of which was in babes under one year old. Henoch believed, and substantiated by postmortem findings, that many atrophic sucklings die from latent tuberculosis. This important fact is overlooked, since: 1. But few nurslings are hospital inmates. 2. Our statistics are derived from hospital records. Biedert states that "the death rate from tuberculosis during the first year is 6.8 per cent., and from the first to the fifth year, 48 per cent." Because of less poverty and better hygienic environment, America furnishes a lower rate. The report published by Holt from the New York Infant Asylum and Babies Hospital, shows only 8 and 14 per cent. death rates respectively, as compared with the 40 per cent. by Muller of Munich.

The localization of the lesions has in part been mentioned and will be dwelt upon *in extenso* by other Fellows of the Academy. Primary pulmonary involvement, in contradistinction to the adult type of disease, is rare in infancy and childhood. Primary glandular and intestinal implication, according to Simonds' statistics and Muller's postmortem statistics, comprise 92 to 84 per cent. of all cases. Their tabulations in regard to other organs are as follows, with Simonds' first and Muller's last:

Lungs	76.2 per cent.	Pia mater	26.8 per cent.
Probably secondary, 92	"	"	24.6
Liver	24.7	Intestines	22.7
"	83	"	38
Spinal cord	20.6	Kidneys	15.6
"	43.3	"	23.3
Pleura	10.3	Bones and joints	10.3
"	6.5	"	7.2
Brain	9	Peritoneum	38
"	2	"	1
Male genitals	2.1	Tonsils and omentum	1

Maas reports a case of tuberculosis of the tubes and ovaries in a five year old girl, with probable source of infection in the navel. Isambert records a case of pharyngeal tuberculosis in a four and a half year old child.

Kossel's observations in the Institute for Infectious Diseases in Berlin demonstrate that 40 per cent. of the one to ten year old patients applying for treatment for diphtheria are suffering from latent tuberculosis, and two-thirds of these cases exhibit enlarged bronchial and mesenteric glands.

Ruge of Berlin cites two cases of primary tubercular tonsillitis with secondary tubercular myelitis. He says: "It is most difficult to differentiate it from simple tonsillar hyperplasia."

Heredity is an etiologic factor only in so far as the transmission of lymphatic, immature, embryonic type of tissue predisposes to all kinds of infections, especially the tubercular. Scrofula seems better thus defined than by the term chronic glandular tuberculosis. Since it has been proven that there is a prenatal seminal, ovarian and intrauterine transmission of this disease, the question of inheritance therefore absolutely resolves itself into one of direct contagion. The germinative theory has been experimentally proven by such men as Landouzy, Martin, Konperoff, Pernise and Sirena: Birch-Hirschfeld and Schmorl were the first to prove its placental origin. Jahni confirmed the presence of tubercle bacilli in the semen of tubercular men, whose testicles were free from these germs. Theobald Smith says: "The tubercle bacillus may pass in semen of the male and infect the ovum directly." Again, "the ovum may be infected by disease of surrounding structures in the female." J. Emmet Holt reports five cases of intra uterine infection. Demme calls attention to a rare case of pulmonary tuberculosis in a twelve day old babe, doubtless of intra-uterine genesis. Berti reports a similar case at birth.

Post natal infection has been known to occur through the milk of a tuberculous nurse. Ritual circumcision is another

established communicating agent. The ordinary infectious diseases of childhood add to the tubercular vulnerability. Infantile habits, such as creeping, placing articles in the mouth, are an added source of danger. Food, particularly milk, the staple dietary of infancy and childhood, here plays an important rôle. It is a well known fact that the lack of food and of dairy inspection laws, lax laws and improper enforcement of the same, account for the presence of from 30 to 50 to even 70 per cent. of tuberculosis in dairy stock and cattle. Lastly, household pets, such as dogs and cats, can communicate this dread disease to their little playmates.

To summarize: The points that I emphasize are: 1. Frequency in infancy and childhood. 2. Localization pertaining to this period of life: rare localization. 3. Etiology, pre-natal, post-natal.

CLIMATOLOGY IN THE TREATMENT OF PULMONARY CONSUMPTION.

Dr. WM. F. WAUGH.—In view of the extravagant claims put forward as to the value of climatic treatment in pulmonary consumption, it may be well to ask what can reasonably be expected from climate. It has not yet been shown that any atmosphere contains elements that are destructive to the tubercle bacillus, nor is any wanting in elements essential to the life of this micro-organism. Every variety of climate has been tried, from the equator to Iceland, the hot, the cold, the wet, the dry, the heavy damp air of the sea-level, and the thin cold atmosphere of elevated regions; even the germ-free depths of the Mammoth Cave have been exploited, but the result has been the same. Everywhere the tubercle bacillus has proved itself capable of existing and operating, of fulfilling its mission, to be fruitful and multiply and depopulate the earth.

The numerous claims made for various resorts as being free from tuberculosis, have even to be modified by the observation, singularly overlooked, that scarcity of consumption coincides with a scarcity of population. While tuberculosis becomes less frequent as we ascend from the sea level, the population decreases as rapidly. Even in Western Kansas, at an elevation somewhat less than 5000 feet, agriculture has proved so unremunerative that many farms have been abandoned. But whenever any locality has acquired a reputation as a resort for consumptives, they have flocked to it in such numbers as to soon infect the soil and the air; so that now the first requisite may be said to be the fact that no other consumptives are present.

Admitting these premises, we must conclude that the only benefit to be obtained from climate is the improvement in the general health, the strengthening of the body in its struggle against the invading bacillus. And in the selection of a resort in each individual case we must apply the personal equation. Some persons thrive in the clear, cold, bracing atmosphere of Minnesota; others can not bear it, but do well in the warm, moist air of Florida. The thin, cool atmosphere of Denver brings health to some, death to others. Many find the most congenial conditions in the region stretching west from San Antonio; while if they were eligible and accessible, the Islands of Polynesia would be the ideal residences for many invalids.

In general that climate is best for the consumptive that permits him to spend the greatest proportion of his time in the open air, and affords the largest number of hours of sunshine.

But climate alone will not kill the tubercle bacillus, and the importance of this method of treatment has been vastly overrated with disastrous results, because it has led patients to rely upon climate exclusively, neglecting more important things such as the personal hygiene, rest during fever, avoidance of fatigue, the digestion, the local treatment of tubercular lesions and the specific treatment, which has now reached a development too important to be ignored. With these matters properly attended to, a consumptive will have a better opportunity for recovery here in Chicago than in any climate on the face of the earth where all other treatment is neglected.

SKIN AND GENITO-URINARY TUBERCULOSIS.

Dr. WM. L. BAUM—I do not care to go into the symptomatology and pathology of the various forms of tuberculosis of the skin and of the genito-urinary organs. Where the skin is concerned there must be a differentiation made in the kind of tubercular infection. There are many cases in which there is characteristic tubercular tissue present, but in which it is not always possible to demonstrate the presence of the tubercle bacillus. It has occurred to me that there might be an allied bacillus, one which is capable of producing the same tissue changes in the skin as the typical Koch tubercle bacillus. This is well shown in a case which was examined by Dr. Klebs some time ago, which occurred in my service in the Cook County Hospital. The patient, a negro, had the typical manifestations of tuberculosis of the skin of the lips. The glands of the neck were examined microscopically and were found so typical of the disease that the case was unhesitatingly pronounced tubercular,

yet no tubercle bacilli were found. This case forms one of a number I have treated with tuberculocidin injections (as prepared by Professor Klebs). The patient showed quite a decided improvement, but a cure has not been effected up to the present time, although he has been under treatment for a long time.

Lupus vulgaris, which is classified as a form of tuberculosis of the skin, is, strictly speaking, not always of typical tubercular formation, probably due to small number of bacilli and slow growth of the focus. There is a tubercular ulceration of the skin which is characteristic and presents a clinical picture that is characterized by a progressive ulceration of the skin, and which does not start with primary nodules as is invariably the case with lupus vulgaris. A case of this kind was under the care of Dr. Moyer some four years ago, who asked me to see the patient. The diseased process occurred on the patient's cheek and was accompanied by marked glandular involvement; for this reason an unfavorable prognosis was made. The large ulcerated surfaces were scraped out with a Volkmann spoon. Large numbers of tubercle bacilli were found. The fungoid granulations destroyed repeatedly with silver nitrate and the surface scraped repeatedly with the sharp spoon; the object of these successive scrapings was to prevent a heaping up of epidermal cells, and to produce a flat, non-adherent cicatrix. The patient's glands decreased considerably in size; she gained twenty-five pounds in weight and is living today. Cases of this kind lead us to conclude that the most virulent forms of tuberculosis of the skin are at times amenable to treatment. The other form of tuberculosis, lupus vulgaris, is too common to need any particular reference at this time.

In genito-urinary work there are frequently found tubercular deposits in the testicles; if they are recognized as such early in the disease, the removal of the offending testicle is probably the best method of treatment. A large number of cases of tubercular diseases of the bladder and sexual organs come to us at a period when they are beyond operative interference. Tuberculosis of the prostate gland, in which the prostate has already been partially destroyed and in which are found frequent hemorrhages, and where the actual presence of tubercular disease by a bacteriologic examination can be demonstrated, reaches the physician at a period when no operative procedure will give even temporary relief, because at that period there is not only a tuberculosis of the prostate and bladder, but extensive tubercular infiltration of the glands. Two such cases have come under my observation in the last two years. One of them was sent to me by Dr. Nelson of Morris, Ill., in May, 1897. The case was very interesting. It occurred in a Norwegian. The Norwegians, many of whom have settled in this country with their families, seem, when infected with tuberculosis, to have the disease in a virulent form. Those who have had experience with these cases say that they are usually hopeless when once infected with tubercle bacillus. This patient was 34 years of age and came to Dr. Nelson for treatment in 1896, at which time he was suffering from epididymitis, and owing to the great swelling of the epididymis the physician made a diagnosis of gonorrheal epididymitis; the patient strenuously denied any infection. A number of months later the patient had a slight sero-sanguine discharge from the urethra, followed by hematuria. About this time, in May, 1897, he was sent to the Post-Graduate Hospital for treatment. Examination revealed the fact that the patient had a nodular growth present in both testicles, and that upon the introduction of an instrument into the posterior urethra he had considerable hemorrhage. He gave a history now of not only having hemorrhages at the end of micturition but hematuria from the kidneys proper with marked pain in the back. He had an average temperature of 99.8 degrees during the first three days after admission. There was no stricture of the urethra and no history of venereal disease. The man is married and has two children. The patient was examined by Dr. Klebs and myself. His lungs were found apparently in excellent condition. An examination of the urine showed a large number of tubercle bacilli with spores, showing a breaking down of tubercular masses. He was immediately put upon tuberculocidin (Klebs). After the first injection the temperature rose to 103.5 degrees. This temperature lasted only about thirty-six hours, when it gradually declined until it reached 99 degrees. He was given a second injection on the third day, when the temperature rose to 102.8 degrees. These injections were made into the tubercular mass in the testicles, first on one side then upon the other. At the end of the tenth day we noticed a slight fluctuation in the right testicle. This fluctuating point was opened and a considerable quantity of cheesy material removed. This material contained large quantities of tubercle bacilli. The patient did not react after the tenth injection. The injections were continued for

a period of four weeks and the patient sent to his home in the country. He worked during the harvest period last year. He has gained in weight and is in good condition. Frequency of micturition, which was a prominent symptom, has been reduced to seven or eight times a day and he does not need to get up at night to urinate.

The second case was an American, 29 years of age, who was admitted to the hospital July 19, 1897, with a temperature of 100 degrees. The lungs were apparently sound. Tubercle bacilli were found to be present in the urine of this patient as demonstrated by Professor Klebs. After the first injection the temperature rose to 102.3 degrees. Subsequently the man had about the same clinical history as the other patient, with the exception that he had marked pain in the apex of the right lung and expectorated considerably after the first injection. The patient apparently recovered, that is, he did not react to injections of tuberculocidin.

In reporting these cases I simply wish to point out that in non-operative cases we have apparently some means of treatment whereby we can hope for some amelioration of the symptoms in tuberculosis in the genito-urinary tract. I would not be justified in saying that these patients are cured, but they are certainly benefited and the results are rather encouraging.

I have here a report of a case in the *Progrès Médicale* of Dec. 11, 1897, by Dauriac, who has used the T. R. tuberculin of Koch, which I will briefly cite. The patient, an accountant by occupation, aged 32 years; brother died of pulmonary tuberculosis; patient had typhoid fever two years ago and has been ailing some since; has been a hard drinker, has had a cough for over a year, the expectoration being yellowish; has twice had hemoptysis; right lung affected. In May, 1897, he had an attack of hematuria which was not abundant, but consisting principally of mucus and small clots. These persisted for a number of days and reappeared from time to time during the treatment. Since May patient micturates very frequently, every twenty to twenty-five minutes. There are no renal pains but a continuous heaviness of the back. At the level of the bladder there is a considerable sense of uneasiness. Appetite is poor; evening rise of temperature, night sweats. Patient very emaciated and had diarrhea. No tubercle bacilli found in urine. In September he was given the first injection of T. R. tuberculin of Koch serum. The injections were continued until November. Urine shows a decrease of the deposits. Patient only urinates four or five times in twenty-four hours, and passes several nights in succession without any desire to urinate. Urine still shows slight trace of albumin. On November 2 the urine was perfectly clear. No more deposits; no more blood. Pains had disappeared. Auscultation shows the condition of the lungs considerably modified, only a slight difference in respiration. Patient eats heartily, but partakes mostly of milk. The milk treatment had previously brought about no amelioration in his condition. December 1 reports a complete cure.

I should not be justified in my cases in reaching this conclusion as the time is entirely too short to make any definite prognostications as regards the future.

SELECTIONS.

Idiopathic Dilatation of Colon; Operation; Recovery.—Mr. Frederick Treves, the eminent surgeon to the London Hospital, has recently performed a notable operation in the removal of the whole of the larger bowel below the transverse colon together with the anus, for the relief of that perilous condition known by the term in the caption of this article. The patient was a girl over five years of age, who had been the subject of painful symptoms, almost from birth referable to intestinal distention, and for the relief of this a first operation had been done in January, 1897, for the establishment of an artificial anus, which was measurably successful for a time. Nine months passed by and the difficulty of maintaining the artificial outlet was present, as is always the case with such openings when made as the present one was made. This necessitated the introduction for so many hours each day of a bent rubber tube which kept the orifice quite patent, but which occasioned the child a good deal of distress. In October, 1897, Mr. Treves resolved to attempt the excision of the colon from the splenic flexure to the anus, as this appeared to afford the only possible prospect of giving complete relief to what was still a distress-

ing condition. This second operation was performed on October 29. By means of an elliptic incision in the skin he isolated and removed the artificial anus, entering the abdomen on each side of the opening. The orifice in the colon was closed by a series of substantial sutures. The gut, which had at one time been so enormously distended, was now of more moderate dimensions, and its point of juncture with the narrow tube which represented the lower part of the colon was still abrupt. The narrow tube had shortened somewhat as the result of removing the distension. The dilatation of the colon extended up to the splenic flexure. Beyond that point the colon was practically normal, although it had evidently been to some degree distended and still showed some hypertrophy of its walls. The colon on the right side was normal and the whole of the greater bowel had a very free mesocolon. Having found that he could bring the left extremity of the transverse colon to the anus, he isolated and ligatured the left colic artery, and having clamped the bowel divided it at the splenic flexure. He then isolated the sigmoid artery and the superior hemorrhoidal vessels and ligatured them. He then excised the gut representing the descending colon, the sigmoid flexure and the upper part of the rectum. He divided the bowel low down in the pelvis below the entrance of the superior hemorrhoidal artery. The child was now placed in the lithotomy position, and having made an elliptic incision around the evidently narrowed anus he proceeded to remove the anus together with the lower and remaining portion of the rectum. The lower end of the rectum having been removed, the transverse colon was brought down into position and secured by a series of close sutures. The gut was conducted into position by four pressure forceps which were passed into the abdomen through the hole in the perineum. The operation was concluded by closing the wound in abdomen without drainage. The child made a speedy and excellent recovery. No sedative of any kind was needed, as little pain was complained of. The only complication was represented by some suppuration between the new rectum and the vagina. This was no doubt due to accidental infection of the tissues while drawing the transverse colon into place. As soon as the child began to run about again this discharge ceased entirely. It is probably safe to conclude that the patient will in due course obtain control over the new anus. Be that as it may, it was clear that the condition previous to the second operation was not consistent with other than a very short life. Mr. Treves has presented the specimen to the Royal College of Surgeons; he describes it as follows: It is quite clear that in this particular instance the dilatation of the colon was due to a congenital narrowing of the lower extremity of the bowel as represented by the segment supplied by the inferior mesenteric artery. This narrowed part exhibited no structural change. Little idea of the immense degree of dilatation of the colon can be gathered from the preparation as it now appears. The junction of the narrowed portion with the dilated part is not so abrupt as it appeared to be before the intestine was removed. At this point of junction there is no mechanical obstruction and no disease of either mucous or muscular coats. In mounting the preparation the structures which formed the anus have been removed. The *Lancet* offers a brief comment on the case, saying "the patient's condition was one where a tremendous operation was the only resource left to the surgeon, for the issue of cases of so-called idiopathic dilatation of the colon is as certainly fatal as the issue of cases of carcinoma of the intestines. That the little patient would have died without prompt surgical interference no one can doubt who reads the notes of the deplorable condition into which she had drifted. The attacks of obstruction of the bowel were growing more frequent and prolonged, the abdominal distension was extreme, no aperients could be used and enemata had lost their effect." All surgeons will be interested in reading the account of the operation as recorded in that journal, the whole story forming a perfect illustration of the remarkable possibilities and resources of abdominal surgery.

Epileptic Colonies Abroad. Before the Harveian Society of London, Dr. A. Turner read a paper on the treatment of epilepsy in epileptic colonies, referring especially to the English colony established at Chalfont St. Peter. This charity had been founded for the purpose of giving employment to those epileptics, both male and female, who, by reason of their disease, were unable to obtain work or who were discharged from remunerative posts on account of epilepsy. The experience of the colony during the four years of its existence pointed to the fact that the younger the epileptic and the sooner he is

admitted after the onset of the seizures the more satisfactory is the result of the general management and régime adopted. The principles which direct the management are simple: 1, removal of the epileptic from the town to the country; 2, regular employment under direction; 3, the maintenance of a well-ordered and regular mode of life, with avoidance of excitement and abstinence from alcoholic liquors; and 4, abundance of good nourishment of a simple nature. The general result is that the fits in the majority of cases diminish both in number and severity, in some cases to quite an extraordinary extent; the physical health materially improves, while the mental condition in all but a few cases shows obvious improvement. Some were sent in as suffering from Jacksonian epilepsy and as being in urgent need of operation; but the fits would cease or subside in frequency and severity so long as the patient remained in the hospital, although medicines were almost entirely withheld. He mentioned the difficulty of treating epilepsy occurring in those past middle life and instanced the case of a man who after being a great sportsman all his life had become epileptic. He would often be seized by a fit while out shooting and would lie down until the attack passed off and then resume his sport. He had taken the responsibility of allowing the patient to continue his favorite pursuits in spite of the obvious danger entailed, thinking that the danger to general health would be still greater were the patient to forego the mode of life to which he was accustomed. — *Lancet*, April 30.

PRACTICAL NOTES.

Varices of the Lower Limbs are successfully treated with Trendelenburg's resection of one or more segments of the saphena between ligatures, but this does not relieve the annoying hard chronic edema. Ledderhose accomplished this and completes the intervention by making from two to five incisions the length of the limb from the root of the foot to the knee, passing through the skin and subcutaneous cellular tissue to the muscular aponeurosis, suturing each incision as soon as made and applying a tight bandage. The limb is held vertically to prevent hemorrhage. — *Semaine Méd.*, May 11.

Application of the Forceps to the Superior Strait in Deformed Pelvis. — Budin reports sixty-four cases thus treated, with no deaths nor morbidity among the mothers; forty-five of the children left the hospital alive and well. Several of the children were already dead or deformed so that death was inevitable. He ascribes three other deaths to the antero-posterior application, which he denounces, advocating the direct application and changing this to the oblique without losing any of the advantage gained. One branch of the forceps is then over the mastoid region on one side and over the frontal on the other. — *French Obstet. Congress*.

Tubercula in Tuberculosis of the Eyes. — Six years ago Zimmermann enucleated the left eye of a patient for ocular tuberculosis. A year ago the other eye became affected in the same way and while the tuberculous patches were cauterized tuberculin was administered, commencing with 1/100 milligram and increasing in a month to 0.02 to 0.03 every second or third day. The patient is now practically cured, and a series of similar experiments on animals confirm the favorable results of tuberculin as a therapeutic agent in ocular tuberculosis in man and beast. — *French Congress of Ophthalmology*.

Intra-ocular Hemorrhage in Youth differs in nature and etiology from the same occurring in maturity or senility. Sudden, relapsing hemorrhage, evidently a form of epistaxis, is best combated by hygienic and tonic measures, quinquina, iron, combined with citric or sulphuric lemonade and ergotin. It is rapidly absorbed. Dyscrasic hemorrhage, frequently brought on by a fit of anger, is treated much the same way. Wet cups

to the temple will also be found useful. If the hemorrhage is secondary to chorio-retinitis, mercurial treatment is indicated, as this affection usually follows syphilitic infection. Apoplectic form hemorrhage into the retina is best combated with one-half to one gram quinin sulphate a day, supplemented by wet cupping the temples and myotics, preferably pilocarpin associated with eserine when the symptoms of glaucoma appear. The prognosis of this latter class is grave.—Abadie, at French Congress of Ophthalmology.

Indications for Petro-Mastoid Evulsion for Dry Chronic Otitis of the Middle Ear.—Operate only when the tuning-fork or acoumeter placed on the skull can still be distinctly heard. Operate early before the lesions spread, and only one ear at a time, selecting the ear with the poorest hearing. The improvement often extends to the non-operated ear. The lower tones are seldom improved, the intervention affecting especially the higher tones and causing the gradual subsidence of the subjective noises. It should not be attempted on elderly people. It requires more or less complete integrity of the fenestrae, but every subject whose aerial audition of the higher tones is not too much diminished should profit by the intervention.—*Presse Méd.*, May 7.

By the Rectal Administration of Large Doses of Sodium Salicylate in Articular Affections, the desired effects are obtained promptly and thoroughly without affecting the appetite and digestion, according to Harlet in the *Nord Méd.* of May 15. He commences with 8 to 12 grams a day in two injections, each in a cup of bran water, adding a little opium or laudanum if necessary. It is completely absorbed in six to eight hours. He then decreases the amount by a gram every second day according to results. After seven grams, but one injection a day is given. He applies locally a 10 per cent. salicylic acid salve, to which a little turpentine or phenic acid has been added, and keeps the patient in bed ten to fifteen days after all pains and swelling have subsided, to prevent relapses or reinfections. This treatment puts an end to the pain in less than three days; the affection leaves no sequelæ, locally or at a distance, and cardiac or gastric complications are avoided. He has been equally successful with it in acute or chronic articular rheumatism or hydro-arthritis, iritis, gonorrheal joint affections, cold pleurisy, etc.

Obstinate Cases of Herpes.—Dr. Oppenheimer (London *Lancet*, April 23), remarks that in his experience herpes genitalis, if not symptomatic of urethral discharge or stricture, is usually due to the decomposition of the smegma præputiale. Ointments mix with the latter and share in the decomposition to which the smegma is so liable, hence there is a contraindication against the use of fatty substances. In his opinion scrupulous cleanliness is the most effective preventive against the recurrence of this troublesome complaint. Hot alcoholic lotions, as eau de Cologne or brandy in water, are quite sufficient. But as the treatment is usually more steadily persevered in when a medicinal lotion is given he is in the habit of prescribing the following lotion: Boric acid 2 dr.; absolute alcohol, 1 oz.; and rosewater to 6 oz. This is to be diluted with equal parts of boiling water and is to be used as a lotion several times a day. A dusting powder containing dermatol and calomel assists the treatment. He usually prescribes the following dusting powder: Calomel, 20 gr.; dermatol, 30 gr.; bismuth subnitrate, 1 dr. This treatment has to be carried out regularly for from four to six weeks and then to be repeated about once or twice a week.

Sinusitis.—Haight's assertion that over one-third of the external diseases of the eyes are due to nasal affections (*vide JOURNAL*, page 1210) parallels de Lapersonne's address at the French Congress of Ophthalmology on the ordinary manifestations of sinusitis. He notes a frequent intermittence in the symptoms of frontal sinusitis, due probably to the temporary obstruction

of the fronto-nasal canal; sometimes recurring neuralgia, with radiating pains in the region, redness of the conjunctiva, photophobia and profuse lachrymal secretion, all aggravated by efforts at accommodation and all subsiding in the course of a few hours to return the next morning at the same time. These cases are preceded by grippe or measles and accompanied by rhinitis. They recover, but recur and tend to chronic frontal sinusitis. In one case the pain, very violent, returned only during menstruation, with dilatation of the pupil and accommodation paresis. He described an acute case in which there were indications of a phlegmon of the orbit, and of meningitis, delirium, temperature 40 degrees C., but the maximum of pain on pressure was in the upper inner part of the orbit and the exophthalmia slightly infero-external, which indicated frontal sinusitis. Perforating the lower wall of the sinus released a purulent accumulation and resulted in a prompt cure with no recurrence. This operation, or trephining the anterior wall, will cure acute sinusitis, but a fistula is apt to persist in chronic cases. These require trephining with fronto-nasal catheterization and destruction of all the anterior and inferior wall of the sinus and of all the mucosa, by curettement or steam. He emphasized the importance of locating all the empyema which may have spread to an adjoining sinus, or be walled off by an abnormal bony partition, or in some abnormal supplementary recess in the palatine apophysis or elsewhere, such as Boulay has observed. Sphenoid or ethmoid lesions should be sought in every case of maxillary sinusitis. They explain a number of orbital complications too often attributed to reflex action.—*Presse Méd.*, May 7.

Grey Oil in the Treatment of Syphilis.—Dr. Touren of the French navy has an interesting article in the *Archives de Médecine Navale* for April, 1898, on the treatment of syphilis by intramuscular injections. At the Moscow Congress Dr. Gaucher of Paris enunciated three propositions: 1. Mercurial injections in the treatment of syphilis should be the exception and not the rule. 2. When injections are employed the soluble salts of mercury are preferable to the insoluble; and 3, if an insoluble salt has to be used, the "grey oil" is the least objectionable. After five months' experience in charge of the Saint Mandrier venereal wards, Dr. Touren is in a position to disagree with the first two propositions, but with the third he is in accord. In civil life, he says, the administration of mercury by the mouth may be best, but in a military or a naval hospital this is certainly not the case. In the first place, there are not only some patients who keep their sores open or create fresh ones wilfully, but also others, more numerous still, who make away with their medicine. Secondly, it is universally acknowledged that in warm climates the digestive tract is peculiarly liable to derangement and should therefore be treated with circumspection. Intramuscular injections enable the physician to administer mercury safely, expeditiously and without any danger of digestive complications, while at the same time they ensure the ingestion of the drug as prescribed. There is therefore no valid objection to the universal employment of this method of treatment. In support of his second proposition Dr. Gaucher asserted that the administration of insoluble salts was a pharmacologic heresy: *corpora non agunt nisi soluta*; but Dr. Touren found that although the symptoms quickly disappeared when a solution of mercury perchlorid was injected, they invariably returned with equal rapidity. In his opinion, a clinical heresy was a far worse evil than a pharmacologic heresy, so he preferred to adhere to the drug which gave him the best results. In Dr. Touren's hands the "grey oil" answered all requirements. The injection was painless, the patient could walk about immediately afterward, salivation rarely showed itself and quickly yielded to an application or two of iodin, diarrhea only occurred once and, lastly, the mercury was absorbed with regularity and very slowly, the latter fact possibly accounting for the permanency of the cure. The formula adopted was as follows: Purified mercury, 20 grams; lanolin, 5 grams; and vaselin, 35 grams. The third of a Pravaz syringe was injected at intervals of fifteen or twenty days, and as a rule three or four injections sufficed to ensure the disappearance of all transmissible symptoms.—*Lancet*, April 30.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JUNE 18, 1898.

TRICHINOSIS, WITH ESPECIAL REFERENCE TO THE INCREASE AND ORIGIN OF THE EOSINOPHILIC CELLS.

In the *Journal of Experimental Medicine* for May, 1898, THOMAS R. BROWN describes two cases, presenting the typic picture of trichinosis, observed in the medical clinic of the Johns Hopkins Hospital of Baltimore. The blood and muscles were subjected to minute examination according to modern methods, and certain facts of great interest have been brought to light. The red blood-corpuscles, counted at frequent intervals during the course of the disease in the first case, gradually increased from 4,200,000 per cubic millimeter at the time of admission to 4,900,000 on the day of discharge, nine weeks later. At the time of entrance the original percentage of eosinophiles was 37, gradually falling to between 10 and 15 per cent. Three weeks later the percentage began to rise and this rise continued steadily for one month, when it reached the remarkably high percentage of 68.2 per cent., so that more than two-thirds of all the white blood-cells were eosinophiles. During this time there was an absolute increase in leucocytes. During the whole period of observation the morphologic character of the eosinophiles was apparently normal. The detailed statement concerning the observations made on the blood with respect to the total number and percentage of the various kinds of leucocytes is clearly displayed in tables, which give the exact figures.

The three most striking points furnished by the study of the blood are: The marked increase in the number of eosinophiles, being 35 per cent. more than has ever before been reported; the coincident fall in

the number of neutrophiles, and the marked leucocytosis. If further observations show this change in the blood to be characteristic, a symptom of the greatest value in diagnosis has been brought to light; a symptom which may perhaps help to clear up some of those cases which are regarded as rheumatic during life, the true diagnosis being revealed, perchance, in the findings of the postmortem table years later.

Pieces of muscle were removed from the right biceps on two separate occasions, and the microscopic changes are carefully described. The changes observed in this case, as well as in tissue obtained from a New York butcher, who died six weeks after the onset of the disease, consisted in marked proliferation of the nuclei, with the formation of muscle cells as well as of distinct vacuoles about the muscle nuclei and a granular degeneration of many of the muscle fibers, and, finally, the interesting and heretofore unnoticed condition, namely, the presence of a large number of eosinophilic cells.

This accumulation of eosinophilic cells in the muscles in trichinosis, coupled with the coincident marked increase in the circulating blood, suggests one way at least in which these cells may arise in the body. There are many views concerning the origin of the eosinophilic cells; all are hypothetic and some are rather far fetched. In Dr. BROWN's study the constant inverse relationship between eosinophiles and neutrophiles, the increase in the former being associated with the decrease in the latter, as well as the similarity in the size and shape of the nuclei of the two varieties, all seem to point toward some intimate relation between the two forms. There is much to suggest that the transformation of neutrophiles into eosinophiles may have occurred in the muscles; thus transitional forms between the two were found in the first piece of muscle examined, and in the second piece, examined two weeks later, there was a greatly increased number of eosinophiles.

The process of transformation of one cell into the other can only be conjectured. The trichinae, on reaching the muscle, cause various tissue changes and produce primarily or secondarily chemotactic substances that lead to a marked local leucocytosis. Polymorphonuclear neutrophiles emigrate and take up into their interior degenerated bits of muscle, and in these phagocytes a change in the character of the protoplasmic granules apparently occurs. Some material may be ingested, material originating from the disintegrating muscle fibers, which brings about a change in the chemistry of the cell, whereby eosinophilic granules are formed. Later these cells wander back again into the circulation and give rise to the marked increase of eosinophiles observed in the blood. This theory would not seem unreasonable, in view of the relatively large amount of muscle tissue in the body.

The study of the second case, which was not quite

so complete as the first, gave practically the same results.

These observations show that there may occur a marked increase in the percentage of eosinophilic cells in the blood in trichinosis; that this increase may be used as a diagnostic sign in this disease; and that systematic examination of the blood should therefore be undertaken in cases with indistinct intestinal, muscular, or articular symptoms, in the hope that perhaps some of the heretofore doubtful cases of this kind may be diagnosed.

THE RESECTION OF THE SYMPATHETIC.

The operative treatment of nervous disorders is an ever present surgical temptation that leads too often to the useless continuance of formidable experiments after the time that their proven insuccess ought reasonably to forbid them. Epilepsy is a condition that has especially incited surgical interference even in cases where the rational hope of cure or even of permanent alleviation is a minimal one. Trephining, excision of cortical centers, ligation of the vertebral arteries, castration, circumcision, the insertion of setons and various other operations have all had their advocates, and reports have been given out of their success, in very many cases, if not indeed in the vast majority, far too soon to be anything but misleading and actually dangerous as therapeutic guides. While the disorder is a sufficiently serious one to justify any operation, however grave, that can afford a reasonable hope of relief, it is certainly a waste of surgery and sometimes it may be also of human life, to indulge in formidable operations when an ample experience should teach us that any lasting beneficial efforts are only very remotely possible if in fact they are possible at all, and such temporary alleviation as may occur is equally likely to be the consequence of very much slighter interventions. The operative treatment of epilepsy, except possibly in comparatively recent traumatic cases, has been generally one of the brilliant failures of surgery.

The latest surgical procedure offered as a cure for epilepsy is resection of the cervical sympathetic, and it is recommended not for this disorder alone but for a number of others, Graves' disease, simple goiter, hysteria, chorea, parietic dementia, brain tumor, cretinism, idiocy and glaucoma. The theory of the utility of the operation is that by excision of the superior cervical ganglia—the cellular relays of the encephalic vasomotors—such a modification of the cerebral circulation will be produced as to affect the cause and course of these diseases. Any more exact pathologic basis for this procedure seems to be wanting and it does not appear at first sight how it is to be beneficial in so wide a range of morbid conditions, in fact, its usage in some of them rather resembles a rash experimentation grounded on no rational considerations.

The cervical ganglion is often necessarily sacrificed in surgery of the neck without any evil results and the operation may therefore be considered as comparatively safe and harmless. If, on the other hand, it was serious, one necessarily involving risk of life, it would be absolutely inexcusable to perform it in some of these conditions without a better reason than the remote possibility of influencing the disorder through a general derangement of the cerebral vasomotors.

The reported successes, even by so strong an advocate as JONNESCO, are not such as to be convincing; a year and half, which is the longest time apparently of observation, is not conclusive as to cure in epilepsy and only the closest observation can absolutely exclude all possible manifestations of the disease. Many reported cases of relieved epilepsy still have nocturnal or abortive attacks, that may be and are easily overlooked and not infrequently what is considered a cure by a careless observer is in reality only a temporary change of type. The beneficial effects in Graves' disease may be real, but, so far, actual and complete cures of the condition do not appear to be generally reported. The fact that the vasomotor disturbances produced by the operation are not lasting, while it makes it less formidable, has also a bearing on its therapeutic value; it is hardly to be expected that a thoroughly chronic morbid habit, so to speak, of the nerve centers is to be completely broken up by a transitory derangement of the circulation.

There may be some question also as to the absolute harmlessness of the operation in all cases, and whether the production of a vasomotor paralysis of the head is necessarily as innocent a proceeding as the advocates of the operation would appear to claim. Cerebral congestion is not ordinarily considered innocuous, and it may not prove so in all cases when it is artificially induced. Injuries of the cervical sympathetic have in times past been credited with producing serious disorders such as insanity, and the inconvenient possibilities of operative interference with its functions ought not to be left entirely out of consideration. Advocates of newly introduced operations are strongly tempted to overlook their failures and to allow their prepossessions to color their judgments; it is therefore well in such cases to accept their results *cum grano*. When, as with this operation we have, with the claims of JONNESCO, CHIPAULT and its other advocates, the contradictory results of DONATH, PÉAN, and others, doubts of its value are certainly justified. In any case our knowledge of the pathologic physiology of the nervous system in this particular direction is too limited as yet to make the operation more than an experiment in the various diseases in which it is recommended, and one the success of which has not yet been satisfactorily demonstrated. As regards epilepsy, idiocy and other chronic and degenerative conditions its insuccess may be *a priori* expected from

our experience with other surgical interventions in these diseases, in spite of the premature claims of its upholders.

CONCERNING THE ABSORPTION OF FOREIGN BODIES THROUGH THE TONSILS, AND ITS RELATION TO THE DEVELOPMENT OF INFECTIOUS PROCESSES.

B. FRAENKEL¹ three or four years ago called attention to the frequency with which acute tonsillitis follows trauma or inflammation of the nasal mucous membrane. Inasmuch as a direct infection of the tonsil through its epithelium is to be regarded as rather difficult, because it has to take place against the exuding stream of lymph and leucocytes, he concluded that the inflammation followed an infection of the nasal mucous membrane, which reached the tonsil by way of the lymphatics. Histologically he was able to show the presence of bacteria in the crypts as well as in the tissues of the tonsil.

Further study of this theory necessitates in the first place the solution of the problem whether the tonsil is able to take up into its interior foreign bodies that come in contact with its lining membrane. The tonsil is generally credited with having a resorptive power, in the text-books, but experimental proof of this power seems to be lacking. In fact HODENPYL concluded from his experiments that the tonsils of lower animals did not absorb bodies through the intact mucous membrane. In order to throw some light upon this question, GOODALE² of Boston undertook certain experiments, to be detailed below. He regarded it from the start as more likely that if any resorption took place at all it would be more apt to occur from the loose lining that covers the crypts, rather than through the compact covering of the surface of the tonsil. GOODALE placed foreign bodies in the crypts of human tonsils, which were more or less hyperplastic, and which it was therefore necessary to remove. When the bodies had remained a certain length of time in the crypts the tonsils were excised and examined microscopically. After a few experiments it was found that a watery solution of carmine served the purpose of the experiments best, because the minute fragments could be recognized in the sections stained with the ordinary nuclear stains, as for instance hematoxylin. Carmine suspended in water was placed in the crypts by means of a blunt silver cannula fastened to a hypodermic needle.

When the tonsils were exercised immediately after the introduction of the carmine into the lacunæ there were no particles to be found in the lining membrane, though the little cavities were filled with the carmine water. After allowing the carmine to remain for twenty minutes in the crypts, fine lines of minute granules were observed running between the cells of

the mucous membrane, in some places extending through a few layers of cells. Particles of carmine were also present in the interior of polynuclear leucocytes. After from forty-five minutes to two hours the carmine was found to have reached from ten to twelve layers of cells below the mucous membrane. Allowing two days for the carmine to be absorbed from the lacunæ the granules were found in linear arrangement between the follicles, lying mostly in leucocytes. There were leucocytes also in the crypts containing granules. In many of these leucocytes the nuclei seemed to be undergoing disintegration. After from five to ten days the carmine was found to have spread more diffusely through the tissues of the tonsils, lying especially in the interfollicular lymph spaces, but also present to a certain extent in the interior of the follicles. In sections of these tonsils, stained to show the presence of bacteria, no micro-organisms were found.

From these experiments GOODALE believes that the following conclusions are warranted:

Absorption occurs normally through the mucous membrane of the crypts of the tonsils.

The absorbed materials pass in through the follicular lymph spaces in the direction of the larger connective tissue septa.

During the absorption the foreign bodies are subjected to the phagocytic action of the polynuclear leucocytes.

Bacteria normally present in the lacunæ are not as a rule found in the tonsillar tissue.

Bacteria that may enter the tonsillar tissue would seem to be destroyed very soon after entrance.

It would also appear that acute lacunar tonsillitis is most frequently caused by the absorption of irritating toxins through the mucous membrane of the crypts, in which the bacteria grow as if in a test-tube.

THE BLOOD IN INFANCY.

One of the last lessons that a physician has to learn is that a child is not a little man. At birth the child is a very incomplete human; it increases in size rapidly during the first few months of extra-uterine life, but this rapid growth of its organs is of course at the expense of the stability, in other words, the resisting power of the organism to abnormalities of all kinds. The blood of infants and young children is especially prone to undergo changes from slight causes and, as a rule, the younger the individual the less the effort needed to throw the blood off its balance, so to speak. For instance, lesions causing a slight leucocytosis or an anemia in an adult would be very likely to bring about a marked leucocytosis or an anemia of high grade in a child.

The blood of a young child differs greatly from that of an adult; indeed, if we were to take the blood of a young healthy adult male as normal, we would be apt

¹ Quoted by Goodale, *Archiv f. Laryngologie*, 7 Band. Loc. cit.

to look upon the blood of a young infant as pathologic. If a specimen of adult blood were similar to that of a young infant we would be justified in concluding that that adult was suffering from some pathologic lesion that was exerting its chief malignant influence upon some of the blood-forming organs. But when we find in all infants these same differences from the adult type, it would be absurd to call infant blood pathologic, especially as it needs but the tincture of time to bring about gradually the condition we are in the habit of regarding as the true standard.

Normal adult blood consists of fluid and solid elements, the latter of which are only of interest to us at present and are known as red and white corpuscles, existing in the relation of one white to five to six hundred red. One cubic millimeter of blood contains approximately five million reds (4,500,000 in the female), and from 5000 to 7500 whites. The red are all of about the same size and shape and are normally not nucleated. The white are divided into several varieties, the division depending upon the age of the cell, young, adult and old leucocytes. The proportion of these one to another is a point of considerable practical importance; the young cells are of two varieties, the small lymphocytes comprising 20 to 30 per cent. of the whole, and the large lymphocytes 5 to 10 per cent.; the adult forms, known as the polymorphonuclear neutrophiles, 60 to 70 per cent., and the old cells or eosinophiles, 0.5 to 4 per cent. Many other points might be stated as regards the corpuscles, but the above are sufficient for the purpose at hand.

To take up the changes in infantile blood in the same order we have enumerated the facts in the adult, we find first that the infant is very liable to have an excess of red corpuscles per cubic millimeter from one-half to as high as one and a half million. A very common change, so common in fact as to be almost constant, is the leucocytosis or increase in the number of whites that occurs during the few first days after birth. Cases have been reported of a leucocytosis of the first day of nearly 20,000, increased by the first meal to over 25,000, gradually receding toward the normal line during the next few days. Leucocytosis occurs after a meal in adults, but never to this great height, another point showing how easily the blood of infants is affected by slight causes. The red corpuscles usually show considerable variation in size and shape, a condition known as poikilocytosis, and not infrequently we find in the peripheral blood that variety of nucleated red corpuscle known as the normoblast, a cell only found in adult blood when pathologic conditions exist. The most important difference, however, is between the relative number of the varieties of leucocytes as shown by the differential count. This count shows that the lymphocytes are relatively more numerous in infants, being present even as high as 60 per cent. This increase is mainly at the expense of the adult forms, which may exist as low as 20 per

cent. When we remember that the adult forms are the only ones of the leucocytes to exert phagocytic action, the readiness with which children become diseased is rendered more easy of explanation. The hemoglobin estimate is not of much importance from a practical standpoint. As the reds are more numerous during the first few days of life, the percentage of hemoglobin would, other things being equal, be somewhat increased. This percentage falls with the lowering of the number of reds and in a somewhat greater degree, so that the hemoglobin after the first week is lower than in the adult. From the comparison then of the blood of infants and adults, we can readily see how unstable that of the former is; how easily it may be acted upon by slight causes, causes that would have little or no effect in the adult. It might also be stated that pathologic lesions that exercise but a slight change in the blood of the latter, are likely to produce in infants swift and terrible changes that result in speedy dissolution, so that it may be taken almost as an axiom that the blood changes by which disease is known in the adult, are in childhood vastly exaggerated, and that the younger the child, the more readily these changes occur and the more pronounced.

CORRESPONDENCE.

Dr. C. Henri Leonard replies to Congressman Corliss, who evidently misrepresents a large number of his constituents.

DETROIT, MICH., June 10, 1898.

C. HENRI LEONARD, M.D., Leonard Block, Detroit, Mich.

Dear Sir:—I am in receipt of your letter with a copy of resolution, and I regret that the medical fraternity should act so *hastily* and without proper investigation.

In the first place, I never introduced a bill in Congress of any name or nature, touching the subject embraced in your resolution.

Secondly, the Hepburn bill, to which you probably refer, I reported to the House by order of the Committee of which I am a member, thereby performing the *duty* devolving upon me as such member.

Thirdly, this measure simply enables the Marine-Hospital service to do more efficiently the work now being done, and does not materially extend the scope of that department.

Fourthly, the measure which the medical fraternity are advocating has not been acted upon by the Committee for the reason that, if adopted, it would entail a *very large expense* upon the Government.

I should be glad to place the physicians right on this subject, and as you seem to be chairman of the committee that prepared the resolution and one of the men who acted without due knowledge, I trust you will *undo the evil* you have created by the publication of *facts not true*.

Very truly yours,

JNO. B. CORLISS.

DETROIT, MICH., June 11, 1898.

HON. JOHN B. CORLISS, House of Representatives, Washington, D. C.

My Dear Sir:—Yours of June 10th duly at hand. In reply to the same allow me to say that your "firstly" and "secondly" are but quibblings over terms. So far as the medical profession of the United States is concerned we do not care

whether you "introduce" a bill, or "report" it to the House; the effect on the profession, if the bill be passed, remains the same. If you have been unjustly "sacrificed" for doing your "duty," why that is nothing that concerns us as medical men. What we are concerned in is your "doings," whether that be in accordance with your so-called "duty," or in accordance with what your medico-political constituents may wish you to do for them. "Duty," then, as you term it, is to be pitted against the powers that help create you a member of the House. The "powers" will see to the "duty" later on, for I assert that the bill you "reported" out, in accordance with "duty" is a bill that is decidedly objectionable, in many particulars, to the medical "powers" that made you a Congressman.

Your "thirdly" is not in accordance, in its conclusions, with conclusions formed by the medical men that have thought over and contemplated the Hepburn bill in its ultimate results. It does not meet with the approval of the mass of the profession in its "enlarged" powers of the Marine-Hospital service. That "power" of the said service, so far as the *general* profession is concerned, is abundantly far-reaching now.

Your "fourthly" is self-condemnatory. The Committee refuse to report the Bill out that has received the endorsement of tens of thousands of medical men throughout the United States, received the endorsement of our medical press, that has received the endorsement of our National, State and County and District Medical Societies, forsooth, because of its "expense!" But the same Committee had no hesitancy about "reporting out" an inimical bill, because it was less expensive! This is a fine *reductio ad absurdum*! Who made the Committee to sit as judges over their creators in the matter of "expense?" Who is paying the expenses of that same Congressional Committee but the ones now asking for a bill to *suit them*, and asking for a bill not to pass that does not suit them, but which may suit a handful of marine doctors—and the Committee, because it is "cheap?"

No, Mr. Corliss, if you and your Committee wish to be set right with the medical profession of this country you will have to undo what you have done, as far as you can, in the expansive provisions of the Hepburn bill, and do not let "expense" be such a bogie-man in the future. I am really glad to learn that a Congressional Committee does sometimes stop at "expense," even if my profession suffers thereby; later on we medical men, when we come to cast our ballots, may think certain United States Congressmen are a little too "expensive" for *our* use, in the National House; then comes *our* time to sit in judgment on "expenses." And when the doctors of a Congressional district get all to work it often proves quite "expensive" to the candidate they disfavor. And right here allow me to say that the *country* members of the profession are more outspoken on this matter, so far as I have heard them, than have been some city members of the medical profession.

I am really inclined to think that party lines, so far as doctors will be concerned, will be forgotten in the desire of attaining the Congressional representation that we have been seeking for the past six years or so. It is possible that this may not prove a National issue on Congressmen, but I think it will soon do so, if we are continually sat down upon on the ground of "expense." We doctors supposed we were working for the good of the country, for the good of humanity in general, else we would not be so in earnest about it. We have been at work too long and too unitedly for us now to sit down and "fold our hands" just because a Committee judge our wants too "expensive," and try to force something along that is against our will, because less expensive.

I am talking thus frankly and plainly, not from personal motives, or likes or dislikes; but as a member of a Committee from our State Medical Society that has been at work upon this matter for some years, jointly with other State and Na-

tional Medical Societies, and I know of the intense feeling of the profession in this matter. It takes a long time to get State recognition of medical matters, and longer to get National recognition; but the time is coming, and that right soon, when the National Congressman may be, as the State Congressman has in the past found himself on several occasions, completely "snowed under" when he has come up for political suffrages.

We medical men are deeply in earnest about this matter, as a common cause of humanity, as well as for our betterment in the handling of epidemic diseases, and in the enlarging our general knowledge of cause of epidemics and means to be adopted to secure their control.

Yours very respectfully, C. HENRI LEONARD, M.D.

Appendicitis.

LONG ISLAND CITY, June 7, 1898.

To the Editor:—I have read with interest Dr. J. F. Baldwin's paper on "Some Unusual Cases of Appendicitis," in the JOURNAL of June 4, 1898, and particularly struck by his reference to the case of complicating general peritonitis (purulent) and his remarks thereon, and reference to Dr. Abbe's statement that the maximum limit of expectancy from an operative standpoint in these cases might be placed at two and one-half days. I have had a number of operative cases of such a character that would tend to substantiate this proposition as a certainty, yet have had several which would negative it, at least in individual cases.

Thinking that it might encourage others to persevere even in very desperate cases of this character, I beg to report the following case, which is the most positive and the facts of which are the clearest in my mind, the patient having been operated on by me on Feb. 22, 1898.

The man, a German about 40 years of age, went to work fairly well on Friday morning early, although he had suffered for several days previously with colic in right side, of which he had had a number of previous attacks, recovering each time after a few days. On the same Friday he was again taken with pain at his work and was brought home with difficulty. I saw him in consultation on the following Tuesday morning, four full days having elapsed. His abdomen was terribly distended and evidently full of pus. I operated at 3 P.M. on Tuesday, but when I placed him on the operating table I noticed the point of maximum swelling and induration was behind and over the lower ribs. I therefore determined to open mid-posteriorly and high up at this site, removing a section of one of the ribs for the purpose of better drainage. I removed about one gallon of pus. The abdominal swelling disappeared in keeping with the evacuation of the pus and I therefore made an incision over the appendix where I originally contemplated, and finding the peritoneum densely thickened and the pyogenic membrane beneath, I opened through and with caution passed a long drainage tube from the greater to the lesser peritoneal cavities, so that the wound could be gently flushed via its natural drainage channels. I made no attempt to find or remove the appendix, as in this class of cases I think it wiser to refrain from more than the most necessary means. The liver and the intestines, both large and small, came into view in the mid-posterior opening, but I protected them, although they were already the site of an active inflammation. The patient has made a good recovery, though somewhat slow owing to the immense drain on his system. The previous and present history of this man were unmistakingly that of suppurative peritonitis consequent on appendicitis, and in the other cases in which I have lost I am convinced too much importance was attached to the appendicitis, which was simply the causative factor in the production of the more grave and rapidly fatal septic condition of purulent diffuse peritonitis. By studying the planes of natural drainage of the pelvic and abdominal

cavities I am convinced that in these cases combined anterior and posterior drainage is the best, and if only one opening is made the posterior would be the better, as a man will not drain rapidly enough through an abdominal opening to remove such large quantities of pus as form in these cases, surprising even a surgeon himself and leading often to the supposition that they might be of longer standing. Some observers have recommended that the tract of the drainage tube in these cases be not washed out, but I think cautious washing after thirty-six or even twenty-four hours, with boracic acid, does good.

I would not trespass on your space save that such an excellent surgeon as Dr. Abbe should have failed to find cases that lived after two and one-half days, and that I am certain that if the essential cause for the operation (septic absorption from pus) is kept in mind, and the appendix kept subordinate in operative manipulations, we stand a far better chance of success.

Very respectfully yours,

JOHN F. BURNS, M.D.

A False Statement.

SPRINGFIELD, ILL., June 6, 1898.

To the Editor:—A concern in Chicago claiming to teach the alleged science misnamed osteopathy, makes the following remarkable statement relative to its so-called courses, in circulars which are sent broadcast over the country:

"Terms of study are so graded and the courses of study so broad and complete that they comply with all the requirements of the Illinois State Medical Board and allow our students two years' credit on a regular medical education. These credits are recognized in any medical college in this country and will be equivalent to two years' work done there."

If by the "Illinois State Medical Board" is meant the Illinois State Board of Health, the assertion made in reference to that body is a lie in the fullest acceptance of the term. It is not true, furthermore, that the "credits" named are recognized in any medical college in this country. On the contrary, it is exceedingly doubtful if a single reputable medical institution will grant any advanced standing whatever to applicants from this and other "colleges" of similar character. Should, however, this be done, it is needless to say that the institution or institutions concerned will receive no further recognition from this Board, and it will be remarkably strange if the various State Boards of Medical Examiners throughout the Union will view such irregular proceedings with complacency.

As the circulars are calculated to deceive the unwary and to cause prospective graduates in medicine to waste two years of time, I will ask you to give this letter a prominent place in the JOURNAL, in order that the facts in the case may be widely disseminated.

J. A. EGAN, M.D.,

Secretary Illinois State Board of Health.

PUBLIC HEALTH.

New Jersey Procedure for Violation of Health Act. The legislation involved in the recent case of State vs. the Board of Health of Woodbridge Township, so far as its sanction is concerned, the supreme court of New Jersey says is anomalous and defies construction; for it inextricably blends together a civil and a quasi criminal jurisdiction. It holds that a jury trial is not permitted by the health act of 1887 (2 General Statutes, page 1638, section 18). And it further declares that to sustain a judgment under that act there must be a conviction in the form prescribed by the supplement of 1888 (2 General Statutes, page 1642, section 41), which expressly requires a conviction as a foundation for judgment, prescribes its terms and provides that it shall be signed by the magistrate.

Railroad Hygiene in Germany.—The new regulations of the Imperial Health Board and Department of Public Works suggest that all passenger cars, especially sleepers on lines running

to resorts for consumptives, are to be finished with smooth walls and ceilings, with no projecting or carved ornamentation and no plush or similar substance on the walls. The cushions and seat backs must be removed from the car at certain intervals and subjected to steam disinfection; the floor space under the seats left free and easily cleaned. Waiting rooms and all roofed-over stations must have the floors washed as often as once a day where there is much traveling and the walls occasionally washed to the height of a man's head. There must be an abundance of cuspidors in cars and stations, as large as possible, and so constructed that they do not easily tip over nor spill their contents. The railroads are to follow these regulations as far as possible at present and conform to them exactly in renovating and constructing in future.—*Münch. med. Woch.*, May 17.

Vital Registration in Connecticut.—In the last *Monthly Bulletin* of the Connecticut State Board of Health, Dr. Lindsley utters a note of despair over the poor success of all his years of hard work to bring about an intelligent and trustworthy registration of the cause of death in his bailiwick. Note the following paragraph: "The heaviest death rate occurred in Thompson, being equivalent to 45 per 1,000 annually of living population. In several instances the cause of death was very indefinite. Among them are the following alleged causes: Debility, paralysis of heart (which is only another name for 'heart failure' and for which a burial permit should not have been given), pulmonary emphysema, pulmonum, whatever the last two may mean. Query: Is it ignorance, or what Artemus Ward called 'just pure cussedness,' that explains such certificates of the causes of death by medical practitioners. It is, of course, impossible to include the above in any classified order." It is indeed a thankless and well-nigh hopeless task, but Dr. Lindsley will need to go right on with his efforts to the end of the chapter. Taking up for a moment Dr. Lindsley's last, or 1896, annual report, which came to hand a few days ago, we find that the mortality of the State was 15,025 in the year 1896 and that in the case of twenty certificates of death the *causa mortis* was not specified by the physician or coroner. In addition to these there were 858 certificates whereon the cause was assigned to "tumors," "debility," and similar vague terms which, as the Secretary says, "were not creditable to the physicians who rendered the certificates."

Typhoid Fever Disseminated by Outdoor Games of Boys.—An English practitioner refers to the fact that many cases of typhoid fever occur in the autumn, and attributes the cause of the disease to games, such as marbles and peg-top, which are played in the street during this time of the year after the cricket season is over. In playing marbles a boy frequently licks his fingers to prevent the marble slipping, and the whip-cord of a top is wet in the mouth for the same reason. In this way germs are conveyed into the alimentary tract. The writer's theory is borne out by the fact that the disease almost exclusively affects boys; girls do not as a rule play at games of that kind. Some weeks ago he saw a boy with typhoid fever, was asked by his parents how he accounted for the attack, as there was no case in the same street, and so asked the mother to let him see the trousers worn by the boy, and showed her how stinking the pockets were; they contained marbles, etc., and dirt from the street. These games may therefore be a great source of danger to children living a town life. But how to remedy the evil is not very easy while such crude methods of doing town scavenging work is permitted to continue. In his own city of Sheffield, he says that he has seen the contents of yard-vaults shoveled out into the streets or roadway in large heaps to be carted away afterward, but leaving behind remainders lodged between the stones of the road, upon and near which the open-air games of boys are daily practiced. He had thought it advisable to point out this source of danger to the young, as he had not as yet

seen any mention of games in any paper or book. Contaminated water in his opinion is not the only source of typhoid and other filth fevers among boys.

Sanitation of Lodging Houses at Boston.—The Board of Health at that city has established an elaborate new set of rules that will probably exterminate a portion of her least desirable houses for lodgers. The air-space, or "sacred breath-cube," has not been fixed at an unreasonably high minimum, namely, at 300 cubic feet per lodger, but much depends on the concomitant measures for ventilating the dormitories. The new rules state that the means for light and ventilation must be satisfactory to the Board of Health and beyond the control of the lodgers. All floors and stairways must be sound, smooth, and either painted or shellacked. There shall be allowed not less than 300 cubic feet of space to each lodger in sleeping rooms. Open and spacious dormitories will be preferred; single or small rooms will be allowed only in exceptional cases, and then only with fire-proof partitions. No carpeting will be allowed on floors or stairways. There shall be not less than two horizontal feet between the sides of any two beds. All bedsteads must be single and of iron. Blankets will be required and "comforters" will be prohibited. No person will be allowed to sleep in his day-clothing. No person who is unclean will be allowed to retire without a bath. Water-closets, one to every twenty lodgers, lavatories and shower-bath, with hot and cold water, all with open plumbing, must be furnished on each floor, and the floors of the same shall be of marble, slate, or concrete. Smoking in sleeping rooms is prohibited. All stairways, fire-escapes, and other means of exit in case of fire must be in accordance with the statutes and ordinances on that subject and to the satisfaction of the building commissioner. Stoves for heating will be allowed only under the most favorable conditions for safety. The use of portable kerosene lamps is prohibited. A reliable person or persons must be in attendance at all hours of the night.

An Interesting Parliamentary Debate on Vaccination.—An animated discussion on a vaccination bill in the English Commons on April 19, brought out a speech by Sir William Priestley, an eminent London practitioner, who was formerly a professor in King's College medical school; it contained a sharp arraignment of the enemies of vaccination. Among other points he stated that it is computed that at present about a third of all the children born in England and Wales were escaping vaccination, *i. e.*, about 300,000 children, and in this connection they could not but recollect the serious object lesson recently presented by Gloucester. The discovery of glycerinated lymph was made in 1891, and yet it had never been adopted systematically in this country. It was most likely, if once adopted, to remove many of the objections and apprehensions of parents, which he had no doubt were very conscientious. It had been adopted in other countries where they had ministers of public health, and where a great deal more attention was paid to the question of public health than was the case in this country. The system had been carried out at Berlin, Paris, Geneva and other centers, and as yet there had been no misadventures. Admitting that harm was done by the practice of vaccination, it was not easy at any time to do a vast amount of good without some modicum of harm. All medical efforts were relative; if they were absolute no one would die. If they were to look into the history of many remedies they would find that misadventures came by their use. It was well known for instance, that no one could avail himself of the administration of chloroform to relieve pain without fear of misadventure. In regard to those domestic remedies, Epsom salts and castor oil, the effects had gone in some cases much farther than had been intended or expected. The great thing in the use of all remedies was to do the greatest amount of good with the least possible harm. It was entirely a question of proportion. Unfor-

tunately, there were always people possessed of what he might be permitted to call the "anti" mind who, with a perverse ingenuity, fastened on the harm and refused to look on the other side of the question. A distinguished scientific friend of his once said he always tried to teach his pupils to think to scale as well as work to scale; but these people who were always dwelling on the harm did not think to scale. They concentrated all their attention upon the mischief and they came signally to grief in their reasoning. Sir William Priestley then went on to express approval of the proposed domiciliary vaccination, although at the same time he hoped that stations would not be abolished altogether. Medical officers under the proposed system would have better means of persuading parents to submit their children to vaccination and of showing that objections were really not valid. It had been said that vaccinators might be very unfavorably received, and in some instances be in danger of violence of antivaccinationists; but in Chicago, among a population made up of all sorts and conditions of men, a system of domiciliary visits had the best possible effect, few children remaining unvaccinated. Some years ago, he had been informed, it was the custom in France to pay a small sum to parents who brought their children to vaccination, and it was surprising to find how parental scruples about danger to children were removed by the few sous paid. It was desirable that some arrangement should be made whereby medical men who vaccinated their own poor patients should receive the fee otherwise paid to the public vaccinator. To the extension of the limit of age he saw no objection so far as danger to children was concerned, for experience had shown that infants under twelve months were unlikely to take smallpox. There were some objections, but they might be overcome. True, there was more risk that the vesicles might be rubbed and contaminated when the child crawled about, and in twelve months removals made the following up of the cases difficult. We might also imitate the practice in Germany, which obtained also in Chicago, and impose some check on the admission of unvaccinated children to school. Antivaccinationists made capital out of the fact that in outbreaks of smallpox many victims had been vaccinated, but they omitted to say how large a proportion had never been revaccinated. It might seem hard to impose an obligation on parents to which they objected and of which they did not see the value. But the object of the State should be the welfare and happiness of the greatest number and the good of the children, above all things, should be the regard of the State as well as of the parents. The danger of allowing a large number of children to remain unvaccinated had been very clearly seen at Gloucester and he would venture to point out that in proportion to the stringency with which vaccination was carried out so was protection furnished to the community. Medical men thought that vaccination was just as essential to the welfare of the child as the provision of food and raiment. If it kept the child from disease, and they believed it would, there ought to be no remission of penalties. At any rate, if there were remission of penalties there ought to be something which was almost equally efficacious. He should be disposed not to remit penalties, but if the parent had conscientious objections to vaccination he would not give it up altogether, but suspend it for a time, say until the school days. This would be a great deal more logical than remitting the penalties. He would make one other suggestion. All parents who insisted that their children should not be vaccinated and who persisted in this course even after being fined once or twice, should be compelled to subscribe to isolation hospitals. Isolation hospitals had been again and again proposed as an alternative to vaccination and no doubt they were the next best thing, though they would not take the place of vaccination.

BOOK NOTICES.

Medical Reports for the Half-Year Ended Sept. 30, 1896. Fifty-Second Issue. Paper. Pp. 44. Illustrated. Special Series No. 2. Published by order of the Inspector General of Customs, Shanghai, China, 1898. Price \$1.00.

This volume contains report on the health of various leading cities of China, especially as to cholera, smallpox and typhus fever, sunstroke, dysentery, enteric fever, sanitary improvements, and cases with full-page plates of parasites; also temperature charts. The various contributors to these reports are:

C. C. de Burgh, E. W. von Tenzelmabn, James H. McCartney, Jno. D. Thompson, E. H. Hart, Alfred Hogg, J. J. Delay.

Sixteenth Report of the Garfield Memorial Hospital.—Paper. Pp. 64. Illustrated. Washington, D. C.: Gibson Bros., 1898.

This report covers the year 1897, contains the report of Board of Directors, Board of Lady Managers, Finance Committee, Medical Staff, and various tabulations and tables of operations performed in the hospital during the year, with classification as to nativity and occupation of patients. There is also a report of the dispensary service and training school for nurses. Numerous full-page plates of the hospital building, wards, etc., are an addition to the volume.

Report of Births, Marriages and Deaths in the Province of Ontario for the year ending Dec. 31, 1896. Cloth. Pp. 212, Toronto: Warwick Bros. & Rutter, 1898.

This report contains numerous tabulations relating to the registrations of births, marriages and deaths throughout the above Province, printed by order of the Legislative Assembly of Ontario. Data relating to other matters of public health are included, and the deaths from diphtheria, tuberculosis and other contagious diseases, with diagram showing comparative deaths from tuberculosis, and table showing deaths from tuberculosis grouped by counties.

Sixteenth Annual Report of the Provincial Board of Health of Ontario. Cloth, pp. 185, Toronto: Warwick Bros. & Rutter, 1897.

This report is for the year 1897, and besides tables and reports concerning other matters of public health, there is a chapter devoted to "Laboratories of Hygienic Research," in which comparisons are made of the work done in various laboratories in the States *i. e.*, Massachusetts and Pennsylvania; a chapter on "Laboratory Results in Serum Diagnosis of Diphtheria," one on "Air Purity as a Measure of Health," and an address on "House Sanitation in Relation to Consumption." Part 3 contains the annual report of various cities in the Province.

Clinical Report of the Rotunda Hospitals. By R. Dancer Purefor, M.D. Paper. Pp. 50. Illustrated. Dublin: Jno. Falconer, 1898.

This report covers the period from Nov. 6, 1896, to Oct. 31, 1897, and contains, besides many full-page plates, diagrams of the gynecologic department, and much data concerning cases in the Rotunda Lying-in Hospital for the above period.

Central Indiana Hospital for the Insane. Paper. Pp. 52. Indianapolis: Wm. B. Burford, 1898.

This, the 49th annual report of the Board of Trustees and Superintendents of the above hospital, covers the fiscal year ending Oct. 31, 1897, and contains matter referring to the administration of the hospital, various tabulations of admissions, discharges and deaths, and statements of revenue and disbursements.

Annual Report of the Department of Health of the City of Cincinnati. Cloth. Pp. 119. Maps. Cincinnati: The Commercial Gazette, 1898.

This report is well gotten up, on excellent paper and contains a diphtheria map, showing the relative distribution of deaths from diphtheria by wards during 1896 and 1897, and a consumption map, giving similar data relative to the distribution of deaths from consumption during this period. Other public health statistics are tabulated in handy form, but the volume lacks an index or table of contents, making it difficult to find the information contained therein.

A Preliminary Arrangement of the Species of the Genus Bacterium. By Frederick D. Chester. Paper. Pp. 94. From the ninth annual report of the Delaware College Agricultural Experiment Station, 1897, Newark, Del.

Part 1, "Contributions to Determinative Bacteriology," takes up characters of bacteria, description, classification, method of growth, species which follow growth on ordinary media, etc. The appendix contains a classification of bacteria associated with diseases of plants, and an index of the most important literature of the species of the genus bacterium.

NEW INSTRUMENTS.

NEW STERILIZER AND DEODORIZER.

BY JACOB R. JOHNS, M.D.
PHILADELPHIA, PA.

Formaldehyde is the gaseous disinfectant, par excellence, being incomparable to sulphur fumes, the chief agent of the past. Practically there are three sources of the gas, requiring vastly different apparatus for its liberation and application. In one form the gas is generated directly from wood alcohol on the principal of retarded combustion. In another form the gas is liberated from the paraform, or solid product. In the third style some form of the aqueous solution of commerce is employed. In all the above, heat is essential. In some the gas is liberated under considerable pressure, thus necessitating a bulky apparatus to guard against explosion. Simplicity of construction and economy are quite generally sacrificed, while in those employing wood alcohol there is always a considerable degree of uncertainty regarding the quantity of gas really involved.

The apparatus I wish to describe is that shown by the illustration. It is the most simple and economic yet suggested, while it is light, easily operated and absolutely free from dangers of any kind. The product employed is the 40 per cent. aqueous solution of commerce, which is decomposed by the heat from an ordinary alcohol lamp. The apparatus is designed especially for sterilizing surgical instruments and dressings, nursing bottles and kindred articles. For apartment disinfection, however small the apartment, the apparatus is totally inadequate. It consists, as will be observed, of a heating lamp, a device for collecting and delivering the gas and a closed sterilizing chamber. One ounce of the solution yields sufficient gas to disinfect the contents of the chamber. In employing this apparatus the author found the gas being liberated in large volumes within two minutes after lighting the lamp and in less than ten minutes the requisite amount of gas was liberated.

The process has the advantage of being perfectly dry, speedy and thorough. Cutting edges are not dulled nor handles injured.

The lamp is invaluable for deodorizing with formaldehyde gas, and when slightly modified by parts supplied may be used to medicate vapors or apply steam heat therapeutically. The apparatus is being introduced by H. K. Mulford Company.

NECROLOGY.

LOUIS E. BERTINE, M.D., (Bellevue, New York, 1881), of Mount Vernon, N. Y., died at his home May 30, the victim of a murderous attack. He was last seen alive May 28, at 11 p.m., when he parted with his brother after a joint attendance upon a public meeting in the Common Council Chamber. Nearly all the gaslights in the streets through which he had passed after leaving the central part of town were extinguished and it

is thought that in the darkness the assassin mistook him for an intended victim. Trephining was without avail and as he did not disturb his family on his arrival home, there only remains as a clue, a faint message sent by himself over the telephone to a police station that he had been struck by an unknown man. After this he was unconscious.

ROBERT TILLEY, M.D., a member of the staff of St. Luke's Hospital, Chicago, June 2, aged 55 years. St. Luke's Hospital staff passed the following resolution:

WHEREAS, Our friend and colleague, Robert Tilley, M.D., has passed from us,

Resolved, That we, the members of the Medical Board of St. Luke's Hospital, in Chicago, wish to extend and hereby do extend to his brother and his family our heartfelt sympathy; and wish to express to his many friends and to the medical profession our profound regret at the loss of an educated and earnest physician, a man ever courteous and kindly a friend just to himself and generous to the faults and failings of others.

JOHN BLAIR GIBBS, Assistant-Surgeon, U. S. A., of Richmond, Va., reported killed at Caimanero, Cuba, June 10.

M. B. COCHRAN, M.D., Iowa City, Iowa, May 29.—Josiah C. Cooper, M.D., Philadelphia, May 30, aged 77 years.—W. H. Drury, M.D., Columbus, Ohio, May 30, aged 65 years.

—E. L. Hutton, M.D., Kansas City, Mo., June 1.—Wm. L. Kennett, M.D., LaCrosse, Wis., May 26, aged 71 years.—J. T. Lindsay, M.D., Yorkville, S. C., May 20, aged 76 years.

—W. H. McNary, M.D., Martinsville, Ill., May 28, aged 77 years.—J. E. Moran, M.D., interne at the Cook County Hospital, Chicago, of Braidwood, Ill., June 1, aged 23 years.—W. C. Roberts, M.D., Maywood, Ill., June 4, aged 45 years.

DEATHS ABROAD.—Wilhelm Grube, formerly Professor of Surgery in the University of Charkow, aged 71 years.—Dr. Amadeo Marianelli, Extraordinary Professor of Dermatology and Syphilography in the Medical Faculty of Modena.

ASSOCIATION NEWS.

Minutes of the Denver Meeting.—We had expected to publish in full this week the minutes of the meeting, but have not received them from the Secretary. We are informed that all the resolutions reported from the Business Committee and acted upon at the Thursday session are still in the hands of the Secretary of that Committee. According to parliamentary usage, when a committee report is presented to a convention, the report then becomes the property of the convention, and unless referred back, the committee has nothing further to do with it. The JOURNAL being the official gazette of the ASSOCIATION, the minutes when published must be accurate, and we are therefore excluded from publishing any partial or reportorial report of the proceedings. Our readers therefore will please understand that the copy has not been furnished us.

Convention Notes.—Many old-timers were missed, but the registration reached nearly 1400.

The plan of holding the general reception at the principal hotel is an excellent one, and added very much to the comfort of the guests.

Owing to the increasing work of the ASSOCIATION, the feeling is growing that it might be well, after the first day, to hold the general sessions at night, and give up the private receptions altogether. These, while occasionally enjoyable, are burdensome and take time that could be spent quite as agreeably in general session.

The enterprise of the Denver newspapers caused the procurement of many photographs and biographies, several weeks in advance of the meeting, which were sufficient in number to enable the appearance of a fresh batch of photographs with new biographies each day. As they had been procured in advance of the meeting, some of them represented gentlemen not present, and in some cases those who had died. One of these papers one day had side by side a picture of a Washington bureau officer with a fulsome laudation, and a picture of the lamented Quimby. "Yes," said one observing it, "The living ass and the dead lion!"

Two ladies were going down the elevator at Brown's: they were discussing a paper on cremation that had been read in the State Medicine Section, one of them had been a widow twice. This lady, who was very handsome, was warmly advocating cremation. "I am not surprised that *you* should advocate cremation," rejoined the other, "for you have husbands to burn." The quiet that ensued was painful.

On the JOURNAL special a lady was talking with a bright young Chicago surgeon. "I wonder," said she, "if Dr. ——— will read one of his 'soul-stirring' papers at this meeting?" "No, madam," replied the young surgeon with becoming gravity, "His paper this year will stir up the duodenum, I believe."

The trip to Idaho Springs was thoroughly enjoyable. At that place the ladies gave a magnificent entertainment, which was on the same grand scale of giant hospitality as the grand mountains by which the guests were surrounded.

The Association Program.—There is on hand at this office a limited number of programs of the Denver meeting of the ASSOCIATION. The book will be sent to any member desiring a copy upon receipt of their request.

Correction.—In the JOURNAL of June 11, second column page 1431, line twenty-one from the bottom, read Floyd W. McRae instead of Alexander McRae.

SOCIETY NEWS.

Indian Territory Medical Association.—At the regular semi-annual meeting of this Association, which convened at Wagoner, I. T., June 1 and 2, the following officers were elected for the ensuing year: President, G. R. Rucker, Eufala; first vice-president, G. A. McBride, Ft. Gibson; second vice president, J. G. Rucker, Claremore; secretary, Leroy Loug, Caddo. The next meeting will be at Wagoner, I. T., December next, the exact date to be fixed by the president and secretary.

MISCELLANY.

Pay of Army Medical Officers.—In answer to a few correspondents the JOURNAL states that in case of war a National guardsman serving in the volunteer service receives the same pay as in the regular army, which is for an assistant surgeon, \$150 a month; a surgeon, \$208.35, and a hospital steward \$45. An acting assistant surgeon under monthly contract which carries with it privilege of resignation at will, receives as a rule \$100 per month.

A Physician's Generosity.—Sir Richard Quain, before his death, presented to the Royal College of Physicians certain very interesting mementoes. Among these were four pieces of plate, one of them being a large silver bowl inset with medals won by him during his collegiate and university career. The most striking piece is a beautiful candelabra fitted for the electric light, which was a gift to Sir Richard Quain from a grateful patient, as also was a silver salver. Another silver salver bears an inscription stating that it was presented to him by the Pathological Society for services rendered to it as honorary secretary.

Only One Inquest Upon Body.—When a coroner has held an inquest upon view of the body, and has returned a verdict and filed the same with the clerk of the circuit court as provided by statute, the appellate court of Indiana decides in the case of the Board of Commissioners of Fountain County vs. Van Cleave, March 31, 1898, that he can not, upon his own motion, hold a second inquest and bind the county for the value of the services of a surgeon who makes an examination of the body at the coroner's request. The court says that the Indiana statute gives the coroner no power to hold more than one inquest, and the fact that the second inquest in question was held at the request of the friends of the deceased person it pronounces not material

for any purpose, except perhaps to show the good faith of the officer in holding the second inquest. Nor does it consider the case changed by the coroner calling the second one returned a supplemental verdict. It says that the length of time to be taken in the inquest proceedings and the thoroughness of the investigation are matters to be determined by the coroner, and if he returns a verdict upon an investigation too hastily made, the matter is at an end so far as he is concerned. This case was transferred to the appellate by the supreme court.

Modifications in the Blood of Syphilitics During Mercurial Treatment.—A large number of persons being treated with intravenous injections of sublimate and benzoate of mercury were examined with great care, and it was constantly found that the blood improved from the first; the red corpuscles and hemoglobin increased, with corresponding decrease in the number of leucocytes, as long as the amount was below 140 to 150 milligrams of sublimate. As soon as this limit is passed, the blood undergoes an intoxication which reduces the red corpuscles and hemoglobin and increases the number of leucocytes. With injections of considerable amounts of weak solutions (10 to 11 c.c. containing each 10 to 11 milligrams) the reconstituting effect on the blood constantly parallels the favorable therapeutic effect on the syphilitic eruptions and general health. With the benzoate, the intoxication commences at the limit of 77 milligrams.—*Presse Méd.*, May 18.

The Massachusetts State Medical Examiners.—We have heard a great deal from time to time here in New York about the Massachusetts system of medical examiners being superior to our system of coroners. Some doubt concerning its excellence, however, is suggested by an occurrence in the Massachusetts General Hospital, reported from Boston on Monday. It appears that a well-known resident of this city who was a patient in that institution committed suicide there on the 13th, inst. The return of his death made to the authorities declared that he died "from organic disease of brain, cirrhosis of liver, etc., laceration of brain and shock to nerves." The fact was that he shot himself in the head, but this circumstance was concealed until disclosed by the undertaker. Suicide is either a crime, the commission of which ought not to be hidden or if committed under circumstances which negative criminality, is so important an occurrence that the concealment of cases of self destruction is of very questionable propriety. We did not suppose that such cases could be concealed by the medical examiners under the Massachusetts statute.—*New York Sun*.

The International Health Exposition at New York. New features are added from time to time to the above display. The public is especially attracted to the sanitary living pictures. Take for example the tenement-house "sweat shop," which is shown in actual operation, in contrast to a model workshop with all modern improvements; a police lodging room, redolent with damp and every kind of foulness, side by side with a model lodging house, such as may be seen opposite Bellevue Hospital; an old country poor-house cell, with a "mad woman" chained to the floor, in contrast to a modern insane asylum ward; a model school in contrast with an unmodel school, and so on with every department of practical hygiene. An interesting exhibit is that of the trained nurses of the world. In this department the latest medical and surgical appliances and all sick appurtenances are exhibited, together with examples of the most practical and best work of the nurses. In this exhibition the nurses of many American institutions have joined forces in order to give their exhibit an educational value to those of their class who have or have not reached their post graduate course. The nurses of other countries have been invited to co-operate. This exhibit contains a modern operating room and an obstetric room as arranged in a private house. There is bed making, cooking for the sick, the way to give medical baths and other lines of work that may properly be demonstrated in public.—*Charities Review*, May.

Death Caused by New Shoes.—About a week after a strong and healthy man commenced wearing a certain pair of new shoes, the friction of one of the shoes against one of his feet unexpectedly produced an abrasion of the skin of one of his toes. He gave the abrasion reasonable attention, but it nevertheless caused blood poisoning in about twenty days, which resulted in the man's death about a week later. Was his death produced "by bodily injuries effected by external, violent and accidental means," as this language would be used in a policy of accident insurance? The United States circuit court of appeals holds that it was, thus affirming the judgment of the court below in the case of the Western Commercial Travelers' Association vs. Smith. On the question of whether the abrasion of the skin of the toe was the natural and probable consequence of wearing new shoes, it says that it must be conceded that new shoes are not ordinarily worn with the design of causing abrasions of the skin of the feet; that an abrasion of the skin is certainly not the probable consequence of the use of new shoes, for it can not be said to follow such use more frequently than it fails to follow it; and that neither can such an abrasion be said to be the natural consequence of wearing such shoes, the consequence which ordinarily follows, or which might be reasonably anticipated.

The Difficulties of a Physician in India.—A medical man writes from Bombay: "Often when we pay our visits of inspections to native homes we find the head of the household sharpening a huge knife, wherewith he has pledged his word to his neighbors to stab the first doctor sahib who enters his household. In one village we entered we found over three thousand of the inhabitants had disappeared and gone to various hiding-places, whence they emerged as soon as we had finished our tour. Of course, we were helpless in the matter. We knew the population was missing, but could not scour the country and conduct our physical examinations by force. It would have been like an Afridi expedition. So we returned with our work only half done."—*Hospital*.

Birds to Produce Tuberculosis Antitoxin.—Prof. E. Behring's announcement, already mentioned, that he has found he can avoid the injurious after-effects of horse and other animal serum, to which consumptives seem especially sensitive, by substituting the serum from birds, is considered a forward stride in this form of therapeutics. The antitoxin furnishes a test for the uniformity and specificity of tuberculosis toxin, whether derived from bacilli washed and dried in the vacuum exsiccator of which one gram is equivalent to 1000 to 1250 M.: "Exsiccator Tb."; or 2, treated with alcohol first and then dried, "Alcohol Tb." of about the same strength as the "Exsiccator"; or 3, derived with alcohol from Koch's old tuberculin "Tub." equals 250 M.; or 4, with alcohol from dialysed culture fluid, "T. F. dial." equals 750 M.; or 5, extracted from the bacilli at 150 degrees C., air excluded, "TD."; or 6, the same as the last toxin, "TD." isolated and concentrated, resulting in a very powerful toxin, "TDr." equivalent to 12,500 M. The various processes do not affect the nature of the toxin. An individual immunized against one is immune to them all, and the saving effect of the antitoxin is identical for them all. He is convinced that the specific toxin of the tuberculosis bacillus is in a tissue, enclosed in a fat- and mucin-containing shell, which can be rejected in isolating the toxin. He reports extensive tests in progress at the veterinary college in Berlin, which seem to promise fine results from the application to animals of the principles of Koch's tuberculin treatment of man.—*Vile Journal*, page 1235; *Deut. Med. Woch.*, May 12.

Functions of the Cerebral Hypophysis.—De Cyon has continued his research on the thyroid gland and hypophysis, and now announces that any pressure, even the slightest, upon the hypophysis, immediately produces an abrupt variation in the blood-pressure and a marked retardation of the heart beat

which becomes much stronger at the same time. This pressure by stimulating the pneumogastric, starts the same mechanism as in the case of the thyroid gland (*vide JOURNAL*, xxix, p. 819), to divert from the brain a dangerous afflux of blood. Electric excitation of the hypophysis produces the same result, but with much greater intensity. In addition to this mechanical role, the hypophysis also produces a chemic substance, hypophysin or phosphoro-hypophysin, destined to facilitate the workings of its automatic mechanism.—*Semaine Méd.*, May 4.

Antipyria Eruptions sometimes assume an erythematous, pigmented form, distressingly chronic. The *Annales de Derm. et de Syph.*, April, contains several instances. Intermittences have been observed in some cases, and in others certain patches have persisted many years, although no new ones have appeared notwithstanding the continued use of the drug. Some deepen in color with every fresh dose. Some cases acquire a tolerance in time and the patches disappear. In some the skin remains supple; in others it is infiltrated. The term antipyrinid is suggested for the group of toxidermias caused by this drug.

Circumscribed Lymphangioma of the Skin and Mucosa develops at the expense of the dermic lymphatic vascular system, although the sanguine vascular system is also involved to a certain extent. Brocq claims a distinct place for it in cutaneous pathology, apart from simple, diffuse lymphangioma, which on the tongue is a variety of macroglossia. It is also to be distinguished from cystic lymphangioma, which includes the serous cysts of surgical pathology, and also from the various kinds of lymphangiectasis which may simulate it both clinically and histologically.—*Ann. de Derm. et de Syph.*, April.

Oriental Regions Having Philippiac Conditions.—Mr. Caspar Whitney, an American globe-trotter of note, has been exploring parts of Sumatra and Malacca, the jungles of which are but little known in this country. Some of his observations in *Harper's Weekly* are of interest to medical men. The jungle is unhealthy, especially during the rainy season, but Mr. Whitney says illness at no time interfered with his hunting plans, although his health was poor a good deal of the time, in spite of the fact that he never slept on the ground: always slept in the smoke of a fire, boiled and filtered all water (which was wretched in quality) before drinking and took quinin moderately. In spite of these precautions he had attacks of both fever and dysentery, but escaped the terrible prostration which usually accompanies them in that climate, probable because of the above precautions coupled with great care as to diet. His precautions would seem to preclude nearly all chance of air or water infection of the malaria. Of mosquitoes he says nothing and it is to be hoped he will do so in later reports of his expedition, as late studies show infection is often carried by these insects.

Naval Preparations at the New York Navy Yard.—Medical Director Bloodgood, retired, U. S. N., of Brooklyn, has been receiving contributions of delicacies at the Brooklyn Navy Yard for the use of sick and wounded sailors in the navy. He reports to the Navy Department that the women of the country are acting in a most generous manner in their patriotic work. A great number of women's organizations have sent quantities of supplies of all varieties to the Brooklyn yard, intended for distribution to the sailors of Captain Sampson's fleet. Jellies, fruit, cans of soups and broths, lemons and considerable money have been received. All of this is to be stored at Brooklyn until the Hospital ship *Solace* returns from the South with her first load of invalids. As soon as the *Solace* reaches Captain Sampson's fleet it is to take on board all the men who are ill and incapacitated for work. She will remain South as long as there is prospect of a naval fight and will only return to the North when her wards are filled with sick and wounded. It is the intention to bring these patients direct to Brooklyn and

to turn them over to the surgeons at that yard. The new naval hospital, just completed at the Brooklyn Navy Yard, is to be utilized for this purpose and it is likely that the first men to be sent there will be those injured in a fight with the Spanish.

Medical Comforts for the Sick of the Army.—The following memorandum from Surgeon General Sternberg of the army embodies his reply to women's relief associations, societies and individuals who have written requesting him to direct their benevolent and patriotic efforts on behalf of the sick and wounded:

"Having received numerous letters from patriotic ladies asking what articles would be most acceptable for the use of our sick and wounded soldiers in the field or in hospital, I have prepared the following memorandum to be sent in reply to letters of inquiry. Money may be sent to the Surgeon-General of the Army as a contribution to the hospital fund of the hospital ship *Relief* and of United States general hospitals. This will be sent to the surgeons in charge, to be expended for delicacies for the sick, such as canned soups, jellies, lemons, oranges, etc. Those who prefer may contribute canned soups, clam broth, orange marmalade, ginger ale, Albert biscuit, Bent's water crackers, and similar articles in hermetically sealed cans for use on the hospital ship *Relief* and at the United States general hospitals at Key West, Fla., Fort McPherson, Ga., Fort Thomas, Ky., and at Fort Myer, Va. Bandages, lint and other surgical dressings are not desired, as these can now be obtained from the manufacturers sterilized for use and of the quality which experience has shown to be best suited to our purposes. Shirts and drawers are provided by the Government, but will be accepted and can be given to convalescents upon their discharge from hospital. Pajamas made of light gingham will be useful for the sick in hospital and on the hospital ship, as they can be worn by convalescents who are able to be out of bed. Long nightshirts of light muslin can also be utilized. Broad bandages of light flannel to protect the abdomen are highly recommended and may be worn to advantage by our soldiers in the field. The articles mentioned may be sent direct to the Surgeon-General of the Army, or to the surgeons in charge of the general hospitals named."

Post-operative Mental Disorders are much discussed just now on both sides of the Atlantic, and the majority incline to the opinion that a mind unbalanced by an operation was not worth much before, that is, mental disorders rarely follow an operation except in the predisposed. Instances have been related of a psychosis following the use of chloroform, and prevented by substituting ether when a second operation became necessary. The confinement and surroundings are frequently responsible for a psychosis following an operation on a person from the country, especially elderly farmers or farmers' wives. Some refuse to operate when there is excessive dread of the operation, and Gerard Marchant observes that mental disorders are almost certain to follow an operation on a "false goorrheic," or a subject with varicocele, or a young neurasthenic woman with the triad: renal ptosis, gastric dilatation and slight metritis. No benefit is ever derived by the patient in these cases, from the operation, and the surgeon only prepares trouble for himself. Le Dentu has had twenty-three cases of psychosis consecutive to an operation, and commenting upon them and sixty-eight in literature, concludes that the assumed connection between such disorders and operations on the genital organs is sustained by the facts observed, adding that there is a certain class of purely cerebral post-operative delirium of which the pathogenesis is still a mystery.

Gleanings.—Four cases of tuberculosis and carcinoma associated, the former evidently the primary affection; three intestinal and one in a lung cavity.—*Virchow's Archiv.*, 148, 149. —Case of subjective parosmia, constant odor of putrefaction perceived, cured by galvanocauterizing the hypertrophied mucosa of the middle turbinate bones.—Lactic acid recommended as the specific for tuberculous lesions especially in laryngeal tuberculosis, preceded by curetting.—Cure of gangrenous diphtheritic angina complicated with mastoiditis, treated by trephining the mastoid abscess. This should inva-

riably be done without reference to the other conditions.—Perforations of the tympanum closed by cauterizing every eight or ten days with trichloroacetic acid, alternating with radiating incisions in severe cases. Hearing improved more or less in forty-nine out of fifty one cases thus treated; deafness aggravated in two.—French Congress of Otolology and Laryngology.—Importance of syphilis as a possible factor in ulcer of the stomach. Instances more frequent than supposed. Specific treatment will cure without an operation.—Paris Acad. de Méd., May 17.—Chorea assumed to be merely the cerebro-medullary manifestations of rheumatic infection in a hysteric or neurasthenic.—Moncorvo of Rio Janeiro.—Spinal ganglia in the lower animals still enclosed in the medulla, descending lower and lower as we ascend the scale, until in man and in birds they emerge through the intervertebral foramina.—*Se-maine Méd.*, May 18.

The Koran not Antagonistic to Vaccination.—Dr. Loir, director of the Tunis Pasteur Institute, in a recent communication to the Academie de Médecine of Paris, noting the prevalence of smallpox in the Algerian Protectorate, stated that in order to get the Mohammedans to permit vaccination it is essential to obtain from the Tunisian religious authorities a declaration that the procedure is not forbidden by the Koran. Dr. Laveran referred to a thesis by Dr. Bechir-Dinguizle, in which he states that, by inquiry among the superior Mohammedan clergy of Tunis, he ascertained that vaccination does not clash with any religious belief of the country.—*Phila. Med. Jour.*

Philadelphia.

APPOINTMENTS TO PHILADELPHIA (BLOCKLEY) HOSPITAL.—This hospital of over four thousand beds, the largest in the United States, is always an objective point to the student while at medical college in Philadelphia, and the different colleges are proud to have their students appointed to the different positions on the medical and surgical staff. At the recent examination ninety-three students presented themselves for the twenty-five vacancies. Of these, fifty-five were from the University of Pennsylvania, twenty from the Medico-Chirurgical College and seven from the Jefferson Medical College. Seven were women, but none of the latter received the necessary average (70) for the appointment. Of those appointed, fifteen are from the University of Pennsylvania and ten from the Medico-Chirurgical College. Dr. Henry C. Chapman, professor of institutes of medicine and medical jurisprudence at the Jefferson College, in speaking for the candidates from that college is quoted as saying: "We had only a 'scratch class,' as this is an off year. Three years ago we changed the course to a four-year one and this is only the fourth year, so we did not expect to have any graduating class at all. The men graduated came from other schools and made a small class of fifty, and only seven presented themselves for examination. Taking the large number of students from other colleges, a very large percentage of them failed, as the examination is a very severe one."

PATIENT WITH A BROKEN NECK LIVES A YEAR.—John K., a lad 9 years of age, living in Camden, N. J., fell from a tree June 9, 1897, sustaining a fracture of the cervical vertebra. The X-ray was applied and confirmed the diagnosis, locating the epicula of bone pressing against the spinal cord. Laminectomy was performed and the fragments of bone removed. The boy subsequently regained consciousness and by means of appliances was able to be carried in an invalid chair about the grounds of Cooper Hospital. Death occurred June 1, 1898.

DR. JOHN GUITERAS FURTHER HONOURED.—Dr. John Guiteras of Philadelphia, Professor of Pathology in the University of Pennsylvania, who was sent to Tampa some time ago by the government, has recently been appointed a brigade surgeon with the rank of major. It is stated that Dr. Guiteras has formulated the necessary health rules for the guidance of troops against contracting the yellow fever while in Cuba. He will accompany the United States army in its campaign for free Cuba, and his services will be of incalculable advantage, owing to the fact that the fighting will be on his native soil.

PENNSYLVANIA HOSPITAL.—At a recent meeting of the staff of the above-named hospital Dr. James W. Wister was elected to fill the vacancy on the staff caused by the expiration of the term of Chief Surgeon W. J. Roe, which occurs July 1. Dr. Clarence de F. Leidy will then be promoted to the position of surgeon.

MORTALITY STATISTICS for the week ending June 4, there were 406 deaths, being a decrease of 3 over the previous week, but an increase of 39 over the corresponding week of last year. Of these, 120 occurred in children under 5 years of age. The causes of death were: from diphtheria 15, typhoid fever 7, scarlet fever 2, against 10, 8 and 4 for the week preceding.

Cincinnati.

ACADEMY OF MEDICINE, May 30.—Dr. Meyer Heidingsfeld reported a case of *nævus vasculorum* which he had treated for two months, by electrolysis. The patient was 17 years of age, *nævus* superficial and of a dark red color situated over the right temple. It presented an elliptic outline in the form of a broad band varying from one half to one inch in width, two and a half inches in breadth and three and a half in length. The center of the ellipse was not involved, save two small circular areas each the size of a half dime. This elliptic band involved the middle of the right eyebrow, upper and lower lid, and the anterior part of the hairy scalp. Treatment: Galvanic electrolysis, two m.a. in strength one-half minute for each insertion of the needle. The latter was inserted parallel to the surface of the skin as superficially as possible. In all there had been nine sittings, each on an average of one and one-quarter hours duration. A 2 per cent. solution of cocaine was injected hypodermically before treatment. The areas in close proximity to the eyelids and those covered with hair were left untreated, and still possess the color and appearance of the original *nævus*. The cosmetic effect has been excellent, the treated area in almost its entirety showing but a vestige of the original color, and contrasting strongly with the cherry red of untreated portions. Inflammatory reaction has been apparently slight, and there are as yet no evidences of cicatrization or deformity, the affected skin being almost as soft and pliable as normal. The same speaker also presented a case of *psoriasis vulgaris* of the nummular type in a child two and a half years old. The efflorescences, which were only of two months standing, were particularly bright red in color, quite large and numerous, and coalescing over certain areas to form plaques four and five inches in either direction, and broad bands several inches in length. These bands followed, for the most part, the lines of cleavage of the skin. The distribution was very extensive, involving all the extremities, a large portion of the body, and nearly the entire scalp. Alopecia was associated. Only one finger nail showed deformity and the knees and elbows were singularly enough but little involved. No history of heredity could be elicited. Discussion was by Drs. Caldwell, Drury, Ricketts, and the speaker. Dr. Ricketts exhibited a specimen of a case of tubercular tumor involving the large intestine about a foot from the ileocecal valve; the mesentery opposite was also the seat of a similar enlargement. Intussusception of the valve into the large intestine had occurred, and had drawn with it an appendix twelve inches in length. Obstruction was not complete. The case was very like that reported by Senn a few weeks ago. Dr. Judkins exhibited a specimen of a case of aneurysm of the arch of the aorta which extended forward and eroded the sternum, producing a large external tumor. The case was presented at the Academy several months ago; the skin was not broken at that time. Several weeks after, the integument necrosed and a slight hemorrhage occurred which, however, was readily controlled by the application of dried persulphate of iron and slight compression. About a week ago a severe hemorrhage took place which was rapidly fatal. Dr. Max Thorner read "Cholesteatoma of the Mastoid."

At the regular meeting of the Society for Original Research, Professor Edwards of the Cincinnati University read a paper on "New Problems in Biology."

THE Tenth Annual Meeting of the American Pediatric Society was held in Cincinnati, June 1, 2 and 3. The evening of June 1, a reception was given by Drs. Forchheimer and Rachford at Chester Park, to which the members of the local profession were invited.

Washington.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended May 21, shows the total number of deaths to have been 90, of which 49 were white and 41 colored. Twenty-one were under 5 and twenty-four over 60 years of age. The principal causes of death were: Diseases of the lungs, 15; nervous diseases, 12; typhoid fever, 3; and one death each from diphtheria, scarlet fever and measles. At the close of the week there were thirty-seven cases of scarlet fever under treatment.

The report for the week ended May 28, shows the total number of deaths to have been 96, of which number 51 were white and 45 colored. Among the principal causes of death were: Diseases of the nervous system, 11; circulatory, 7; genito-

urinary, 9; respiratory, 23. There were two fatal cases of typhoid fever, diphtheria, measles, whooping-cough and la grippe. There were 41 cases of diphtheria and 41 cases of scarlet fever under treatment at the close of the week.

DRS. LOUIS J. BATTLE, Will Fred M. Barton, S. Clifford Cox, Francis R. Hagner and John L. Norrie, have been appointed physicians to the poor at \$360 per annum.

MEDICAL SOCIETY.—At the recent meetings of the Society the following papers were read: M. F. Thompson, "Hydrophobia;" Dr. Burnette, "Gangrene of Eyelids and Cheeks, with Destruction of Both Eyeballs Resulting from Human Bites;" Dr. Acker, "Empyema and Purulent Pericarditis, case and specimens;" G. W. Johnston, "The Necessity of Accuracy and Uniformity in Chemic Laboratory Investigations;" G. Wythe Cook, "Cancer of the Stomach, case and specimen;" W. W. Johnston, "Sarcoma of the Lung, case and specimen;" Report of Committee on Public Health; Dr. Reyburn, "The Use of Expectorants;" Dr. Butler, "Nasal Polypus;" Dr. Lamb, "Hydronephrosis in a Calf; specimen."

WASHINGTON OBSTETRICAL AND GYNCOLOGICAL SOCIETY.—The 282d meeting of the Society was held on the 20th ultimo at the residence of Dr. Balloch. Dr. Van Rensselaer reported the removal of a large uterine polypus from a patient over 90 years of age.

EMERGENCY HOSPITAL.—Dr. Jeunemann's term of resident physician having expired, Dr. Fife, the first assistant resident, will be promoted to the office of resident physician. The competitive examination recently held to fill the office of first and second physician, resulted in the selection of M. W. Glover of the Georgetown Medical School and F. H. Mohart of the Columbian Medical School.

Dr. Ralph E. Gallinger, son of the Senator from New Hampshire, is quite ill at the New York City Hospital. Dr. Gallinger is one of the Assistants to the Staff of the Hospital.

Dr. Francis Leber has resigned from the Assisting Staff and joined his regiment at Key West, Fla. He has recently been appointed an acting Assistant Surgeon in the U. S. Army.

Miss Margaret Schaffer, the nurse in charge of the sterilizing department of the Hospital has resigned, to accept a position as Army nurse in the Hospital Corps of the D. A. R. Miss Schaffer has the distinction of being one of the four nurses first called to the Military Hospital Corps.

WOMAN'S CLINIC.—At the recent meeting of the Woman's Clinic, the Hospital was reported to be in a flourishing condition: 617 patients were treated in March and 460 in April. Miss Eva Simonton, Sup't. Central Dispensary and Emergency Hospital was elected a member of the Board of Directors. Dr. Isabell Haslup was elected a member of the attending staff.

EPISCOPAL EYE, EAR AND THROAT HOSPITAL.—The report of the work done in the Hospital for the past four months shows 530 patients were treated, of whom 249 were white and 236 colored. Two thousand and thirty visits were made to the different departments. Seventy-one patients have been received into the Hospital, of which 39 were free and 32 pay patients. The sum of \$2256.16 has been collected for the Hospital since January 1; 92 operations have been performed during the past four months.

CONTRIBUTIONS TO MILITARY HOSPITALS.—Surgeon-General Sternberg, in reply to numerous inquiries from persons desiring to make contributions to the wounded soldiers in the field, has issued the following general reply: Money may be sent to the Surgeon-General of the army as a contribution to the hospital funds of the hospital ship *Relief* and of the U. S. general hospitals. This will be sent to the surgeons in charge, to be expended for delicacies for the sick, such as canned soups, oranges, etc. Those who prefer, may contribute canned soups, clam broth, orange marmalade, ginger ale, biscuit, water-crackers, and similar articles in hermetically sealed cans for use on the hospital ship *Relief* and the U. S. General Hospitals, at Key West, Fla.; Fort McPherson, Ga.; Fort Thomas, Ky., and Fort Myer, Va. Bandages, lint and other articles are not desired as these can be obtained from the manufacturers sterilized for use and of the quality which experience has shown best suited. Shirts and drawers are provided by the government, but will be accepted and can be given to convalescents upon their discharge from hospital. Pajamas made of light gingham will be useful for the sick in hospital and on the hospital ship, as they can be worn by convalescents who are able to be out of bed. Long nightshirts of linen muslin can also be utilized. Broad bandages of light flannel to protect the abdomen are highly recommended and may be worn to advantage by our soldiers in the field. The articles mentioned may be sent direct to the Surgeon-General of the army or to the surgeons in charge of the general hospitals named.

DR. AINSWORTH RECOVERING. Dr. F. C. Ainsworth, Colonel U. S. Army, who has been seriously ill for the past month, is considerably improved, and will shortly resume his duties in the War Department.

Miss Amanda J. Armistead of the Central Dispensary and Emergency Hospital, has been appointed by Surgeon General Sternberg, nurse to the Hospital Relief Corps of the D. A. R. This is the second nurse appointed from this institution to the Army Corps.

MICROSCOPICAL SOCIETY.—At the meeting of the Society, held on the 31st ultimo, the program of the evening was: Exhibition of a high power projection lantern with arc light and slides including living objects.

WASHINGTON OBSTETRICAL AND GYNCOLOGICAL SOCIETY.—At the 283d meeting of the Society, held on the 3d instant, Dr. William M. Sprigg read a paper on "Pessaries;" an interesting discussion followed.

Colleges.

THE COLUMBIAN UNIVERSITY, Washington, D. C., held its seventy-seventh annual commencement June 1.—The graduating class of the University College of Medicine, Lynchburg, Va., numbered forty-nine at the annual commencement, May 26.—The Woman's Medical College of the New York Infirmary for Women and Children held its thirteenth annual commencement May 26.—The Atlanta Medical and the Southern Medical Colleges of Atlanta, Ga., have united.

Societies.

The following recent meetings are noted:

Indiana.—Vigo Medical City, Terre Haute, June 2.

Maine.—Maine Medical Association, Portland, June 1-3.

Minnesota.—Minneapolis Academy of Medicine, June 1.

Missouri.—Medical Society of City Hospital Alumni, St. Louis, June 2.

New Jersey.—Atlantic County Medical Society, Atlantic City, May 26.

New York.—Medico-Chirurgical Society, Syracuse, June 2; Otsego County Medical Society, Cooperstown, May 31; Queens County Medical Society, Mineola, L. I., May 31; Ulster County Medical Society, Kingston, May 31.

Ohio.—Butler County Medical Society, Hamilton, June 1; Clark County Medical Association, Springfield, June 2; Cleveland Medical Society, May 27.

Medical Colleges in the United States in active existence Jan. 1, 1898, to which recognition, partial or complete, is accorded by the Illinois State Board of Health:

ALABAMA.—Medical College of Alabama (Med. Dept. University of Alabama), Mobile.

ARKANSAS.—Arkansas Industrial University, Medical Department, Little Rock.

CALIFORNIA.—California Medical College, San Francisco. College of Medicine of the University of Southern California, Los Angeles. Cooper Medical College, San Francisco. Hahnemann Hospital College, San Francisco. Medical Department of the College of Physicians and Surgeons, San Francisco. Medical Department of the University of California, San Francisco.

COLORADO.—Denver Homeopathic Medical College and Hospital, Denver. Gross Medical College, Denver. University of Colorado (Colorado School of Medicine), Boulder. University of Denver, Department of Medicine, Denver.

CONNECTICUT.—Yale University, Department of Medicine, New Haven. **DISTRICT OF COLUMBIA.**—Georgetown University, School of Medicine. Howard University, Medical Department. National Medical College, Medical Department. Columbian University, Medical Department, National University.

GEORGIA.—Atlanta Medical College, Atlanta. Georgia College of Eclectic Medicine and Surgery, Atlanta. Medical College of Georgia, Augusta. Southern Medical College, Atlanta.

ILLINOIS.—Bennett College of Eclectic Medicine and Surgery, Chicago. Chicago Homeopathic Medical College, Chicago. Chicago Physio-Medical College, Chicago. College of Physicians and Surgeons, Chicago. Dunham Medical College, Chicago. Hahnemann Medical College and Hospital, Chicago. Harvey Medical College, Chicago. Herling Medical College, Chicago. Illinois Medical College, Chicago. Jenner Medical College, Chicago. National Medical College, Chicago. Northwestern University, Medical School (Chicago Medical College), Chicago. Northwestern University, Woman's Medical School, Chicago. Rush Medical College, Chicago.

INDIANA.—Central College of Physicians and Surgeons, Indianapolis. Fort Wayne College of Medicine, Fort Wayne. Medical College of Indiana, University of Indianapolis, Indianapolis. Physio-Medical College of Indiana, Indianapolis.

IOWA.—College of Physicians and Surgeons, Keokuk. Homeopathic Medical Department, University of Iowa, Iowa City. Iowa College of Physicians and Surgeons, Des Moines. Keokuk Medical College, Keokuk. Medical Department, University of Iowa, Iowa City. Sioux City College of Medicine, Sioux City.

KANSAS.—College of Physicians and Surgeons (Medical Department Kansas City University), Kansas City. Kansas Medical College, Topeka.

KENTUCKY.—Hospital College of Medicine, Louisville. Kentucky School of Medicine, Louisville. Louisville Medical College, Louisville. Southwestern Homeopathic Medical College, Louisville. University of Louisville, Medical Department, Louisville.

LOUISIANA.—Medical Department, Tulane University, New Orleans. New Orleans University, Medical Department, New Orleans.

MAINE.—Maine School of Medicine at Bowdoin College, Brunswick.

MARYLAND.—Baltimore Medical College, Baltimore. Baltimore University, School of Medicine, Baltimore. College of Physicians and Surgeons, Baltimore. Johns Hopkins Medical School, Baltimore. Southern Homeopathic Medical College and Hospital, Baltimore. University of Maryland, School of Medicine, Baltimore. Woman's Medical College, Baltimore.

MASSACHUSETTS.—Boston University School of Medicine, Boston. Harvard University Medical School, Boston. Tufts Medical College, Boston.

MICHIGAN.—Detroit College of Medicine, Detroit. Homeopathic Medical College of the University of Michigan, Ann Arbor. Michigan College of Medicine and Surgery, Detroit. University of Michigan, Department of Medicine and Surgery, Ann Arbor.

MINNESOTA.—University of Minnesota, College of Medicine and Surgery, Minneapolis. University of Minnesota, College of Homeopathic Medicine and Surgery, Minneapolis.

MISSOURI.—American Medical College, St. Louis. Barnes Medical College, St. Louis. Beaumont Hospital Medical College, St. Louis. Central Medical College, St. Joseph. Emsworth Medical College and Hospital, St. Joseph. Homeopathic Medical College of Missouri, St. Louis. Kansas City Homeopathic Medical College, Kansas City. Kansas City Medical College, Kansas City. Marion Sims College of Medicine, St. Louis. St. Louis College of Physicians and Surgeons, St. Louis. St. Louis Medical College, St. Louis. University Medical College, Kansas City. Woman's Medical College, Kansas City.

NEBRASKA.—John A. Creighton Medical College, Omaha. Omaha Medical College (Medical Department University of Omaha), Omaha. Lincoln Medical College of Corner University, Lincoln.

NEW HAMPSHIRE.—Dartmouth Medical College, Hanover.

NEW YORK.—Albany Medical College, Albany. Bellevue Hospital Medical College, New York. College of Physicians and Surgeons of Columbia University, New York. Eclectic Medical College of the City of New York, New York. Long Island College Hospital, Brooklyn. Medical Department Niagara University, Buffalo. New York Medical College and Hospital for Women, New York. New York Homeopathic Medical College and Hospital, New York. New York University Medical College, New York. Syracuse University College of Medicine, Syracuse. University of Buffalo, Medical Department, Buffalo. Woman's Medical College of the New York Infirmary, New York.

NORTH CAROLINA.—Leonard School of Medicine, Raleigh.

OHIO.—Cincinnati College of Medicine and Surgery, Cincinnati. Cleveland College of Physicians and Surgeons, Cleveland. Cleveland Homeopathic Medical College, Cleveland. Eclectic Medical Institute, Cincinnati. Laura Memorial College, Cincinnati. Medical College of Ohio, Cincinnati. Medical College of the Western Reserve University, Cleveland. Miami Medical College, Cincinnati. Ohio Medical University, Columbus. Pulte Medical College, Cincinnati. Starling Medical College, Columbus. Toledo Medical College, Toledo.

OREGON.—Medical Department Williamette University, Salem. University of Oregon, Portland.

PENNSYLVANIA.—Hahnemann Medical College and Hospital, Philadelphia. Jefferson Medical College, Philadelphia. Medico-Chirurgical College of Philadelphia, Philadelphia. University of Pennsylvania, Department of Medicine, Philadelphia. Western Pennsylvania Medical College, Pittsburgh. Woman's Medical College of Pennsylvania, Philadelphia.

SOUTH CAROLINA.—Medical College of the State of South Carolina, Charleston.

TENNESSEE.—Chattanooga Medical College, Nashville. Medical Department University of Tennessee, Nashville. Meharry Medical College, Nashville. Memphis Hospital Medical College, Memphis. Tennessee Medical College, Knoxville. University of Nashville, Medical Department, Nashville. Vanderbilt University, Medical Department, Nashville.

TEXAS.—Medical Department University of Texas, Galveston.

VERMONT.—Medical Department of the University of Vermont, Burlington.

VIRGINIA.—Medical College of Virginia, Richmond. Medical Department University of Virginia, Charlottesville. University College of Medicine, Richmond.

WISCONSIN.—Milwaukee Medical College, Milwaukee. Wisconsin College of Physicians and Surgeons, Milwaukee.

The above list, which has been carefully revised, includes every reputable medical college in the United States known to the Illinois State Board of Health. Of the institutions named, several are recognized unconditionally during all years, others are in good standing in certain years only, a neglect to comply with the requirements of the Board causing conditional recognition during some periods, and to a not inconsiderable number is granted conditional recognition only during all years of existence. Specific information in the case of any college named, or in relation to extinct institutions will be forwarded on request. To existing institutions not named, no recognition whatever is given by the Illinois State Board of Health.

J. A. EGAN, M.D., Secretary.

CHANGE OF ADDRESS.

Buchard, W. M., from Lemon City, Fla. to Uncasville, Conn.
Brown, J. R., from 8 Sterling to 1614 Central Ave., Indianapolis, Ind.
Campbell, C. H., from Iowa City, Iowa, to Osceola, Neb.
Campbell, A. M., from Detroit to Hazlett Park, Mich.
De Lee, J. B., from 3318 Indiana Ave. to 3634 Prairie Ave., Chicago, Ill.
Emmerson, R., from 813 Harrison St. to 301 E. 31st St., Chicago, Ill.
Frahm, M., from Chicago to Tuscola, Ill.
Gage, M. R., from Phoenix, Ariz. to Sparta, Wis.
Gotsch, G. A., from 303 S. Lincoln St. to 837 W. North Ave., Chicago.
Hotvedt, I. J., from 907 to 912 21st Ave., So. Minneapolis, Minn.
Jaquith, W. A., from 491 LaSalle Ave. to 1184 Wilcox Ave., Chicago, Ill.
Josephson, D. V., from 155 S. Sangamon to 317 W. 12th St., Chicago, Ill.
McTerry, from Des Moines to Pioneer, Iowa.
Mason, L. D., from Brooklyn, N. Y. to Greenwich, Conn.
McEwen, from 191 S. Lincoln St. to County Hospital, Chicago, Ill.
Pearse, H. E., from 1018 E. 15th St. to 312 Rialto Building, Chicago, Ill.
Pleth, V., from 759 to 740 W. North Ave., Chicago, Ill.
Rouch, J. C., from Primroy to 811, Tenn.
Spaulding, H., from 3351 Indiana Ave. to 3133 Rhodes Ave., Chicago.
Sylvester, H., from Mineral Point to 132 Grand Ave., Milwaukee, Wis.
Smolt, C. E., from Newton to Hutchinson, Kan.

Smith, P. C., from Indianapolis, Ind. to Charlotte, Mich.
Scott, J. W., from Springfield to Venice, Ill.
Thompson, J. P., from 14th and H St. to 804 17th St., N. W., Washington, D. C.
Teigen, M. O., from 408 Nicollet St. to 660 Temple Court, Minneapolis.
Thorpe, C. W., from Denver Athletic Club to McPhee Building, Denver, Colo.
Warner, J. W., from New York to 19 York Ave., Saratoga, N. Y.

LETTERS RECEIVED.

American Embossing Co., Buffalo, N. Y.
Baltimore Medical College, Baltimore, Md.; Bell, F. C., Chicago, Ill.; Breedlove, J. W., Fort Smith, Ark.
Chicago Eye, Ear, Nose and Throat College, Chicago, Ill.; Chaille, S. E., New Orleans, La.
Dewey, C. R., Coloma, Mich.; Dulomy, R. W., Jonesboro, Tenn.
Foster, G. A., Wilkesburg, Pa.; Frazier & Co., N. S., Aurora, Ill.; Fuller Advertising Agency, C. H., Buffalo, N. Y.
Grant, Thomas Page, Louisville, Ky.
Hennacy, Geo. W., Clinton, Iowa; Hektoen, L., Chicago, Ill.; Hatch, W. Grant, Prairie City, Ill.; Henry, C. W., Coon Rapids, Iowa.
Johns, J. R., Philadelphia, Pa.
Larew, Jno. T., St. Louis, Mo.; Lehu & Fink, New York, N. Y.
McCurdy, S. L., Pittsburg, Pa.; Mansfield, L. F., Watertown, N. Y.; Malster, K. M., Omaha, Nebr.
Newell & Heldman, Chicago, Ill.
Opie, Thomas, Baltimore, Md.
Pearson, W. W., Des Moines, Iowa; Philadelphia Medical Journal, Philadelphia, Pa.
Richardson, H., Mount Hope Retreat, Md.
Smith, W. O., New Castle, Pa.
Vanghan, V. C., Ann Arbor, Mich.
Wells, F. A., Garden Creek, N. C.; Wellner, Hermann, Concord, N. H.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from June 1 to 10, 1898.

Acting Asst. Surgeon James H. McCall, U. S. A., will proceed from Huntsington, Tenn., to Ft. McPherson, Ga., and report for duty in the general hospital at that place.
Acting Asst. Surgeon W. P. Chamberlain, U. S. A., will proceed from Washington, D. C., to Ft. Monroe, Va., and report for duty.
Capt. Frank R. Keefer and Paul F. Straub, Asst. Surgeons, will report to the commanding General, Dept. of the Pacific, for duty with the expedition to the Philippine Islands.
Acting Asst. Surgeon Thomas R. Marshall, U. S. A., will proceed from Richmond, Va., to Tampa, Fla., and report for duty with troops in the field.
Acting Asst. Surgeon George H. Penrose, U. S. A., will proceed from Ft. Douglas, Utah, to San Francisco, Cal., and report for duty with the Utah batteries for the expedition to the Philippine Islands.
Acting Asst. Surgeon A. S. Condou, U. S. A., will proceed from Ogden, Utah, to Ft. Bayard, N. M., and report for duty.
Acting Asst. Surgeon T. S. Dabney, U. S. A., order assigning him to Tampa, Fla., is revoked, and he is ordered to Jackson Bks., La., for duty.
Acting Asst. Surgeons Richard P. Stroug and Henry E. Wetherill, U. S. A., ordered to Tampa, Fla., for duty.
Acting Asst. Surgeon Edward Sebreiner, U. S. A., ordered to Ft. McPherson, Ga., for duty in general hospital.
Acting Asst. Surgeon Frederick McG. Hartsook, U. S. A., ordered to U. S. hospital ship "Relief."
Capt. Alfred E. Bradley, Asst. Surgeon, ordered to Camp Alger, Falls Church, Va., for duty with Second Army Corps.
Capt. Edgar A. Mearns, Asst. Surgeon, ordered to Camp George H. Torney, Chickamauga National Park, Ga.
Acting Asst. Surgeon James B. Ferguson, U. S. A., ordered from Olivia, Minn., to Ft. Yellowstone, Wyo., for duty.
Acting Asst. Surgeon Rupert Norton, ordered to Ft. McPherson, Ga., for duty in general hospital at that place.
Capt. Frederick P. Reynolds and George J. Newgardeu, Asst. Surgeons, having reported in person to the Surgeon-General of the Army, are ordered to Tampa, Fla., for duty with cavalry division.
Capt. James D. Glennan, Asst. Surgeon, is relieved from duty with Sixth U. S. Cavalry, and ordered to Camp George H. Thomas, Chickamauga National Park, Ga.
Capt. William P. Kendall, Asst. Surgeon, is relieved from duty with the Ninth U. S. Cavalry, and will proceed to Camp George H. Thomas, Chickamauga National Park, Ga.
Capt. Henry R. Stiles, Asst. Surgeon, ordered to Tampa, Fla., for duty with Fifth Army Corps.
Capt. William Stephenson, Asst. Surgeon, is relieved from duty with Fourth U. S. Infantry, and ordered to Camp George H. Thomas, Chickamauga National Park, Ga., for duty with First Army Corps.
Capt. Henry I. Raymond, Asst. Surgeon, is relieved from duty with Thirteenth U. S. Infantry and ordered to Camp George H. Thomas, Chickamauga National Park, Ga.
Capt. Charles F. Kieffer and First Lieut. Powell C. Fauntleroy, Asst. Surgeons, ordered to Tampa, Fla., for duty.
Capt. Ogden Rafferty, Asst. Surgeon, ordered to Key West, Fla., for duty in the general hospital at that place.
Capt. William C. Gorgas, Asst. Surgeon, ordered to duty on U. S. hospital ship "Relief."
Capt. John S. Kulp, Asst. Surgeon, is relieved from duty in Dept. of the Columbia, and ordered to report in person to the Surgeon-General of the Army for further orders.
Capt. Edward C. Carter, Asst. Surgeon, will proceed to Chattanooga, Tenn., for the purpose of establishing a general hospital in the Chattanooga Park Hotel, to be known as the Letter General Hospital, in accordance with such instructions as he may receive from the Surgeon-General of the Army.
Capt. William D. Crosby, Asst. Surgeon, will report to the Major General commanding the Dept. of the Pacific, for duty with the expedition to the Philippine Islands.
Acting Asst. Surgeon Edwards C. Pory, U. S. A., ordered to Tampa, Fla., for duty.
Acting Asst. Surgeon J. R. Shannon, U. S. A., ordered to Tampa, Fla., for duty.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, JUNE 25, 1898.

No. 26.

ANNUAL ORATION.

THE ESSENTIAL OF THE ART OF MEDICINE.

The Oration in Medicine delivered at the Forty-ninth Annual Meeting
of the American Medical Association held at Denver,
Colo., June 7-10, 1898.

BY J. H. MUSSER, M.D.
PHILADELPHIA, PA.

The closing years of the eighteenth century and the early years of the nineteenth century marked an epoch in medicine as transcendent for its welfare as the events of the past decade bespeak for the glory of the medicine of the future. In that epoch was witnessed the passing of the old; the dawn of the new. A long farewell was being said to schools of medicine and systems of pathology and false methods; a timorous but cordial welcome was extended to the beginnings of that which culminated in the realism of the nineteenth century. It is true, as echoes of the past, Brunonianism, Broussaisism, the Stimolo and Contrastimolo of Rasori, and subordinate "isms" furnished exercise for the expiring idealistic intellect, and seemed to condone for the pernicious therapeutics of the early periods of this century.

Although the reform period extended over the seventeenth and eighteenth centuries, the death agony of idealism began about the period we have indicated. It is true that Harvey and Willis and Glisson, and Malpighi, and Schwammerdam, in the seventeenth century supplemented the labors of the early anatomists and bid fair to found a science of medicine. In this earlier century, most important of all, arose the Baconian system of philosophy. Nevertheless the sway of the imagination and the rule of theory never seemed more powerful. Deductive philosophy seemed to be at its height. Instruments of precision had not been employed up to this time, and the collateral sciences were not sufficiently developed to invoke aid from them in the investigations of physiology and pathology. It is not to be wondered at that the indefinite data secured by observation restricted to the unaided eye, and to the touch, should lead them to indulge in elaborate classifications of disease and to refinements in symptomatology which now serve only to amuse and appal. Under these circumstances the Iatro-chemical, the Iatro-mechanical, the Mechanico-dynamic schools, the schools of Animism and Vitalism and Solidism waxed and waned, and out of them the Brunonian, Rasorian, Hahnemannian and other fallacious schools were born.

Along with pseudo-scientific systems, artificial classification reached its highest pitch in that of Sauvage. His system included ten classes of disease, each subdivided into several orders, and some as many as 295 genera and 2400 species of disease (Park). For Cullen, four classes with 149 genera were enough to encompass the field of pathology.

Time forbids entering into detail concerning the

theoretic and speculative modes of treatment which grew out of such specious pathology. Again there was a rise and fall. To Willis again (seventeenth century) credit must first be given for approaching the rational and scientific in therapeutics (Leech), as in physiology and anatomy. Sydenham displayed the most astute scientific habit of mind in urging simple observation and simple treatment, in fully recognizing the healing power of nature, and in removing the immediate cause of the disease. Observation and experience was the central idea of his method, a revival of Hippocratic methods, which to this day influence medical thought. It is interesting to know on the authority of Leech that, with the exception of emetics, purgatives, bitters and carminatives, very few of the drugs he and Willis employed had the powers they claimed for them, and most of them have lapsed into a deserved oblivion. Both these great men were moderate polypharmacists, as many as eighteen herbs only being used in one prescription. Their rivals and successors, however, far surpassed them in the number and character of the ingredients of the formulæ they employed. With the growth and decay of systems in the eighteenth century—the death agony lapsing into the nineteenth—flourished and declined, remedial measures debilitating or stimulating, alterative or evacuant, according to the specific view in vogue. Venesection followed shortly and lingered long; stimulation raged, polypharmacy grew apace and then, when results did not warrant practice, change in the type of disease was invoked (Allison and others) to fit fact to theory.

Theoretic systems came to an end with the promulgation of the systems of Brown, Broussais and Hahnemann. A universal skepticism arose; the expectant treatment in France, and in Germany "Nihilismus," were the refuge of scientific inquirers (Benett). Therapeutics, with the development of chemistry and the growth of physiology and pathology, became rational. But, further reference, with your permission, will be made to rational therapeutics later.

In the meantime it must not be forgotten that Stahl and his followers were among the earliest skeptics, denying the efficiency of medicine, even doubting the value of opium and cinchona. Let it be recorded here likewise, as an admonition to those who oppose and a hope for those who favor, that as early as 280 B. C., perhaps by others earlier, Erasistratus urged gymnastics, exercise, diet and baths, in preference to drugs, and that the echoes of his refrain never died out. Asclepiades discarded all violent remedies and relied on hygienic means alone. Moreover, from time immemorial climatic treatment was extolled. Coming to later days, among the not a few essays on climatic treatment, Rush's description of the advantages secured by long journeys on horseback for the treatment of consumption is as fascinating as the many writings of this almost myriad-minded man.

It is quite impossible to leave the deductive philosophers, the theorists, the speculators in the medicine of the eighteenth century, without an inquiry into the methods employed by them to secure data upon which the diagnosis of disease was based and therapeutics determined. "What a patient said and what the physician saw and felt was all a case of disease had to tell him," Mitchell eloquently states. Such was the limitation of the inquiry. Instruments of precision were not used, chemic analysis not made, while biologic studies were not dreamed of. It is true Paulus Ægineta had employed sounds and specula; Santorini counted the pulse and used the thermometer and balance; Boerhaave used the thermometer in the axilla, and the lens; Floyer and Haller marked seconds with the watch. Their use was forgotten or neglected. This is not to be wondered at when we recall the obtuse state of mental receptivity that allowed Avenbrugger, who invented percussion and described it so pithily and exhaustively in 1760, to wait until 1808 for Corvisart's recognition of its value.

Examination of a patient included, careful scrutiny of the exterior, the face and features, the eye, the protruded tongue, the state of the extremities in comparison with the trunk, the color of the skin; observation of the temperature and degree of moisture or dryness of the skin and the varying pulse revealed to the touch; a note of the decubitus, the movements of muscles and of the naked-eye characteristics of the urine, the vomitus and the feces. Changes the character of the voice, and delirium, stupor and other gross evidences of impaired cerebral action were described. The eye saw more than it sees today, mayhap, but it looked through the glass darkly; the touch was more sensitive, but not as sensible. Generally it was "observation gone minutely mad." (Mitchell.) Fifteen minutes would have been ample time to make a complete objective examination of the patient, unless the refinements of symptomatology, conjured by the imagination, furnished opportunity for the lapse of longer time. The accuracy of the diagnosis depended more upon the extent of the experience of the physician and his knowledge of medicine acquired by reading than upon precision in the method of obtaining facts upon which to base a diagnosis. Such diagnosis was often an intuition, as harmful then as now, and hence attained without it being possible to state the process of reasoning by which the end was secured. Think of it, that the number of the pulse and the respiration is rarely referred to in the writings of Rush and Cullen, and that Corvisart "On the Heart," says nothing of the frequency of the pulse, and Laënnec makes no mention of the breathing rate. In truth, actual diagnoses were not made, but instead, a symptom, such as jaundice, dropsy or fever was described. It is not to be wondered at, as previously indicated, to appraise the patient and establish his own authority, theories of disease were uppermost in the physician's mind, and deductions from such theories utilized to establish diagnoses and formulate lines of treatment. Cullen stated that theory could not be separated from practice, hence it was unimportant which came first, and that, therefore theories could control observations.

If guessing the truth from ill-defined data is an intuition, and so-called "rule of thumb" methods an inspiration, it can then be said that the medicine of this period reached the acme of perfection of such methods of diagnoses; from this time its displacement by inductive methods began.

But medicine as a science was no higher nor lower than cognate departments of knowledge. Law, it is true, was a science then as in the days of Justinian. Theology was not removed from the deductive methods of reasoning, although there was reaction and quickening. Metaphysics, because dealing with the unknowable, was deductive, but physics and astronomy were casting off their swaddling clothes. The former had just run the gauntlet of deductive philosophy, after the brilliant deduction of Black, whereby the theory of latent heat was established, one of the very few deductions which afterward was proved directly and inductively to be true. Chemistry was a new-born in the sciences under the brilliant accouchement of Lavoisier; geology had grown through the labors of Buffon and Rouelle, but it was only welcomed to the circle of the sciences by the genius of Cuvier. Botany, groaning with the classification of Linnaeus, was emerging into light by virtue of the brilliant generalizations of Goethe in vegetal physiology (the awakening of evolution) and of Desfontaines and Jussieu in structural physiology. Berzelius and Lisle were organizing mineralogy. Cuvier was associating anatomy with geology and laying the foundations of paleontology. The brilliant dictum of this great man that the "first question in science is always a question of method" resulted in sweeping away the artificial classifications in natural history as of Linnaeus in botany, and in removing natural sciences from the hands of the observer into that of the experimenter. Buckle's remark, "the consequences of which has been the attainment of that precision and accuracy of detail which experiment alone can give and which is every way superior to such popular facts as observation supplies," none the less applies to natural history, then and now, than to a minor department of it, the science of medicine. Cuvier, he further remarks taught naturalists the true path of inquiry by accustoming them to a close and severe method, and by teaching them to despise vague descriptions. How well we should take this to heart in our present day labors—close and severe method.

The latter half of the eighteenth century also shows the industrial arts flourishing to a high degree, but carried on alone by "rule of thumb" methods and by experience. Brewing, cheese-making, milling, butter-making, tanning, metallurgy and other industrial arts were conducted without scientific method, and the art transmitted from father to son, from master to apprentice after years of trial and oft, from repeated failures, of tribulation. In spinning and weaving, in iron-making and other manufactures, great machines, instruments of precision in industrial arts, were bringing about changes which were destined to modify the social fabric of the world.

In fine it may be said, science ceased to be deductive, and was fast growing to be inductive and experimental. Medicine too was becoming inductive and realistic; its art scientific and rational.

For more than nine and ninety months the gestation of modern medicine was in progress during this century. Morgagni was laying the foundation of morbid anatomy. (1761) the "great" Haller had brought light out of darkness in establishing experimental science and laying the foundation of modern physiology, but to Hunter in the eighteenth, and Pinel and Bichat in the late eighteenth and early nineteenth century, we owe our foundations of medicine. Hunter could not put aside the deductive methods of reasoning entirely, but in pathology he employed both induc-

tive and deductive methods alike, as Buckle points out, attaining the truth more nearly with the former method. Certain it is that to Hunter we owe the development of *method* in pathological inquiry, observation and experiment being the handmaidens with which he gathered the innumerable data which make him the "equal of Aristotle, Harvey and Bichat and the superior of Haller and Cuvier." To Pinel we owe the substitution of analytic for synthetic methods and the origin of systematic diagnosis by the careful construction of symptoms, while to Bichat, the "Napoleon of Medicine," to whom is due the foundations of modern morphology, we as clinicians owe "the establishment of that large and sweeping innovation which opens up a new view of thought and creates fresh resources." He of all others overthrew speculative tendencies in medicine.

The progress during the present century, familiar to all, has been marked by the employment of inductive methods of reasoning in the departments of physiology, pathology and clinical medicine. By the results of such methods and the development of a scientific habit of thought, the science of medicine, which is that of physiology in its broadest sense, the physiology of health as well as the physiology of disease, including the effects of drugs, can well fill its minor place in the science of biology. The old cry of the uncertainty of medicine, the unscientific character of the art of medicine, can not be held up to us. No Montaigne can at this day hurl the shafts of ridicule and satire that stung to the quick and stimulated honest doubt in the sixteenth century. Well do we know, ourselves, our limitations as well as our power, and with becoming modesty do we uphold the claims of medicine as a science. If science is "knowledge gained by systematic observation, experiment and reasoning; knowledge, co-ordinated, arranged and systematized," well fortified is he with cynicism who has the hardihood to maintain the contrary.

To sketch the struggles by which this firm height has been attained would be to reiterate that which is familiar to you and to detain you far beyond the measure of your desserts. Its history would be the story of the labors of Bailie, Laënnec, Cruveilhier, Rokitansky, and others in forming the foundations of morbid anatomy, and of Virchow, Cohnheim, Koch, Lister, Pasteur and hosts of others in both continents, creating the science of morbid physiology. Its history would be an account of the application of scientific habits of thought in experiment, observation and analysis. It would show the dependence of it upon the major sciences, if they may be so termed, chemistry, physics and biology, whereby instruments of precision and methods of chemical, physical and biological research became essential in the practice of the art of medicine, in diagnosis and in therapeutics. It would show that we have attained precise knowledge of the origin, course, mode of recognition and control of many diseases; that we can predict the occurrence of their daily phenomena, as the astronomer predicts the appearance and course of a comet. From our knowledge of etiology we can create disease at will, but more triumphant of all achievements, the glory of the century, we can deliberately and positively, and hence scientifically, prevent disease. We have learned that diseases are events exhibiting disturbances of the processes of physiology; that involution, degeneration, decay and death are normal events, as are evolution, growth and birth. The great

postulates of Koch, the brilliant steps in inductive biology of Pasteur and of Lister leading to preventive measures, the scope of which is almost inconceivable, is akin to the conceptions of Newton and Dalton in physics.

Such advances were only attained by the master spirit of the naturalist. We are wont to forget that the use of instruments of precision, guided by the method and scientific habit of thought of the naturalist as physician brought us to this great height. Our debt to the naturalist must never be forgotten. The lesson we can the better learn from a closer analysis of the position of modern diagnosis and modern therapeutics in modern thought. It would be unjust however not to give credit to that scientific honest doubt and scientific receptivity of truth which is characteristic of the Anglo-Saxon intellect, by reason of which the philosophical structures of this era have been raised.

It must be remembered that the closing years of the nineteenth century are marked by the prevalence in all fields of mental activity of that habit of thought which has grown out of inductive philosophy. In whatsoever domain we make investigation we find that which may be called a scientific habit of thought prevails. In theology it has extended to such a degree as to alarm, without just grounds for such alarm, those who have the hardihood to cling to old habits attendant upon the deductive science. Here it now appears almost iconoclastic. It need not, on the one hand, be the occasion for fear; nor on the other, for the creation of antagonism. For experience has shown that the exposition of truth in this manner only the more firmly builds the temple which it is thought might be destroyed; while from many standpoints we know the utter futility of attempting to prevent the progress of knowledge thus attained. In history inductive philosophy has revolutionized methods, and wrought out a philosophy which harmonizes human action with organic law. In sociology, although as yet tentative, it is aiding in the solution of problems which will contribute to human happiness. Chemistry has verily grown to an exact science, and the exposition of the "Periodic Law" looks to greater exactitude in the science of pharmacology.

The conservation and correlation of forces in physics and the conception of evolution in biology are the triumphs of inductive philosophy and the glory of this great era.

Diagnosis.—The department of clinical medicine is an art as well as a science and includes diagnosis and therapeutics. I have elsewhere stated the limitations of the inquiry in diagnosis one hundred years ago. Then one-fourth, one-sixteenth of the time now employed sufficed to gather all data. It is not necessary to rehearse to you the expansion of the inquiry at this day. To establish any diagnosis perhaps days may be required. After securing subjective data, there are required the skill of the chemist to analyze secretions; of the physiologist to examine the blood and apply the physical instruments of precision so necessary to elucidate the facts derived from the visual apparatus, the nervous system, the circulation and he respiration; of the biologist, to study the life properties of the parasite that may be the ruthless invader of tissues. By these means, however, and by the use of auscultation and percussion; by the use of modern methods of direct vision with specula and lens and mirrors; or of indirect vision, with photograph

and Roentgen rays, or more precisely still by bringing the inaccessible to view by exploratory operation or exploratory puncture, precision in diagnosis has reached a degree over which exultation can only be calmed by awe at the possibilities of further expansion. It is seen that anesthetics and asepsis brought to us a timely aid in diagnosis—exploratory operation. To be more explicit and more emphatic, the accompanying table will more strongly display the scope and position of modern diagnosis.

DISEASES RECOGNIZED BY SCIENTIFIC METHODS—INSTRUMENTS OF PRECISION.

1. Malaria.
 2. Leprosy.
 3. Relapsing fever.
 4. Dysentery (amebic, providing the ameba is recognized as the cause of disease).
 5. Tuberculosis—bacteria and tuberculin.
 6. Diphtheria.
 7. Asiatic cholera.
 8. Tetanus.
 9. Actinomycosis.
 10. Glanders—serum test Malein.
 11. Cancer
 12. Sarcoma
 13. Leukemia.
 14. Various parasites, as filaria.
- } in certain localities.

DIAGNOSIS RECOGNIZED BY SCIENTIFIC METHODS, WITH LIMITATIONS.

1. Typhoid fever (*may be certain*).
2. Various forms of pyogenic infection if in blood.
3. Various forms of meningitis from lumbar puncture.
4. Chlorosis.
5. Pernicious anemia.
6. Gonorrhea.
7. Effusions by exploratory incision.
8. Growths by exploratory operation.
9. Eye diseases.
10. Laryngeal diseases.
11. Ear diseases.

It is thus seen that whereas in 1800 only a few diseases could be positively recognized, now as many as fourteen in internal medicine alone can positively and beyond peradventure be diagnosticated, while eleven more with limitations that the scientific mind can appreciate can be affirmed to exist. What more forcible statement can be made to show the position of the science of diagnosis. Still more enforced however, when we remember that in addition the list can be swollen tenfold, if we would include the groups of the diseases of special organs, as eye, ear, etc., and those of internal organs which can be recognized by a scientific consideration of an orderly procession of the facts. These are those first, of etiology brought out in the social history; second, of the history and course of previous diseases, and third, of the evolution of the disease under consideration, united to, fourth, the data derived by an objective examination of the patient when in addition diagnosis by exclusion is judiciously employed—a close and severe method in gathering data. Under the above circumstances, scurvy, myxedema, exophthalmic goiter, hemophilia, the inflammations or degenerations of most organs and many other affections are not be overlooked.

What a difference in comparison with the diagnoses of bygone days. In a given case of suspected malaria, five minutes examination of the blood settles the diagnosis and wipes out the necessity of all considerations of the manifold subjective symptoms of the disease, and the objective symptoms which often were questionable facts from imaginary postulates. A conception of diagnosis or the breadth of research necessary to establish

such diagnosis shows that time is gained to the patient, lost to the physician. It is not any wonder, therefore, that a general practitioner must have a corps of trained assistants or laboratories at his command. While the patient has gained in the precision and rapidity of a diagnosis, the gain of a community is much greater. The instant recognition of an epidemic forewarns and forearms. Instead of waiting for a large group of cases, and a series of autopsies, the biological diagnosis of one case settles all doubt.

It is thus seen that an essential in the art of diagnosis is skill in the use of instruments of precision and the application of a scientific habit of thought. It is further seen that with the incoming of scientific precision there is the outgoing of so-called art. Diagnosis by intuition, by careless "rule of thumb," methods, by an appeal to an experience which is incoordinated, unsystematized and unarranged, is as little trustworthy as the shifting sands of the Sahara.

Diagnosis has thus become in many directions scientific, precise and positive. It has minimized the value of experience and eliminated deductive reasoning as a factor in the art of medicine, which in consequence has grown more practical because more scientific, and less theoretic because more practical. In diagnosis the art of attaining the end has been replaced by the scientific method of securing this end—the large element of uncertainty based upon imperfectly gathered and unreliable data, replaced by the small element of possible error of method in securing positive data.

THERAPEUTICS.

Venesection, polypharmacy, treatment based on deductive generalizations, swayed medical practice a hundred years ago. The beginning transition to rational therapeutics has been outlined, and it is important to note that such change was the result of the projection of scientific habits of thought into the field of the therapist, and the appreciation by him of the facts and principles of biology. The first rude awakening took place when the therapist was asked to define what he was treating, to place on a scientific basis the knowledge of the nature of the disease against which he was exercising his power. He had to state with definiteness and precision, as far attainable as possible, the nature of the processes contending over the treatment of which the theorists gave birth to a jargon of medical literature as vast in its extent as in its indefiniteness, and by which the mental vision of the artisan was obscured. It was rational for him, in order to answer this question properly, to study the natural history of disease; to learn from the study of a large number of cases the origin, the progress, and the decline of diseases, and their effects upon the economy when death resulted. The promulgation of studies of this character was made more readily possible by the establishment of hospitals and dispensaries in the seventeenth and eighteenth centuries, by means of which the aggregations could be classified and compared. The practitioner, in the on-rush of duty, could not retain from month to month the recollection of a type of disease, for such comparison. The multiplicity of the cases, and the enlarged extent of the experience, the presentation in the ward perhaps of a dozen cases of a given type at one time, coupled with the habit of recording the history of cases, made the conduct of such studies possible. Out of this inquiry arose the Paris Pathological

School and the Vienna School of Medicine. Although none the more forceful, the labors of the former seem to dominate the medical thought of the first half of the century. The numerical method of Louis contributed vastly to our knowledge of the course of disease and the effects of remedies. The methods that he supported to such an extreme as to lead to their own injury, resulted in the production of essays in the natural history of the specific ailment, indicating that disease had an evolution and involution which, if undisturbed, tended to a natural cure. Thus, the self-limitation of many ailments was worked out. The essays of Bennett and Wilks and Gull and of Bigelow and Flint awakened a judicious skepticism. The application of the analytic methods of various forms of treatment brought about the same result. Expectancy became the rule of the hour. That disease was an expression of morbid physiology, the natural tendency of which was to self-restoration, became evident to all.

The accumulation of knowledge, and its array in mathematic language, led to the interjection of other sciences that of mathematic philosophy, as involved in the theory of probabilities and of the science of statistics. Cold, formal mathematics gave little ground for theory to stand upon.

The analytic study of a large number of prescriptions by Martindale, and later by Patch, carried out for another purpose, disclosed the fact that, after all, a great deal of our boasted therapeutics as to the number of drugs employed, was brag and bluster. A study of Martindale's analyses shows that the total number of times the drugs, which were called for more than thirty times, were used was 31,664 in 12,000 prescriptions; but 8,588 of these were employed externally or as excipients. Thirteen drugs alone in various preparations were prescribed 10,054 times, nearly one-half of the entire number, excluding externals.

Of course, the great array of agents employed, the fact that many perished with the setting of the sun that had arisen on the day of their birth, was called attention to by many observers, and led to further doubt. Then skepticism came about in another way. The more incurable the disease the greater the number of drugs vaunted for its relief. Hence, upward of 90 were advised at one time for epilepsy; hosts for exophthalmic goiter and for other affections, uncontrollable in days gone by. In scanning the literature of the "drug-house" one can too often set down as worthless the drug that "cures" many diseases, or one can fix in his mind as incurable the disease that has a multitude of remedies recommended for its cure. The pretentious and formidable array of drugs that the manufacturers thrust at us daily is alike as uncomplimentary to our knowledge and common sense as it is an evidence of the infantile state of their therapeutics. I counted 554 Galenic drugs alone in a price-list, not having the time to calculate upon inorganic and other preparations. Such drug-firms cater surely to that period of the evolution of a doctor wittily epitomized by Radcliffe: "When young, he had 20 remedies for every disease; when old, 20 diseases for which he had no remedy." And thus it has come about that the individual judgment of the effects of treatment of individual cases, unless hedged in by limitations, is of very little value unless supported by laboratory experiments.

Calm, deliberative study on the lines established by the schools referred to, whereby the physiology and

the pathology of the disease were acquired, as well as knowledge of its course in new environments, led to the production of many essays on the limitations and the powers of drugs. Moreover, such studies led us to know the nature of the disease, the action of the drug in health and its action in disease. It seems most absurd that such processes of ratiocination did not occur long before the advent of physiologic therapeutics.

Then occurred to many, as they went along in practice, how small the number of drugs actually employed. Repeated papers have been published upon subjects that went to show how few drugs were actually employed, and how small the number upon which reliance could be placed. Moreover, drug-accounts and the requisition-blanks of hospitals and army and navy dispensaries showed what few drugs were actual necessities. A critical analysis of a modern work on therapeutics reveals the fact that the certainties are few. The number of drugs that are scientifically curative can be counted on the fingers of the two hands.

The criteria upon which to base statements of the value of drugs are those of experiment and observation. The number from which by experiment and reason we know produce a definite effect are limited, types of which are seen in opium, belladonna and alkalies.

Another group of observers, basing their criticism upon very patent scientific grounds, led us to understand that we could not judge of the action of a drug if it was administered in conjunction with other remedies. Hence, assaults on polypharmacy began. The most reasonable injunction that simplicity in therapeutics is essential prevails largely at the present time, but that the assaults must continue the following prescription, devised on the twenty-eighth day of May, in the year of our Lord 1898, by a writer of some prominence in therapeutics, witnesses—the drugs only are enumerated: sodium salicylate, potassium acetate, ammonium acetate, fluid extract of euphorbia, peppermint water, compound tincture of benzoin, compound tincture of capsicum, tincture of nux vomica, syrup of tolu. (I trust the recording angel will wipe out the sin of theft from a prescription-file). Here is another for an infant 9 months old, with nostrums from three other bottles, and the wonder was the child died. It contained quinin sulphate, protonuclein, pepsin, hydrochloric acid, arsenic chlorid, and one or two excipients.

The therapist may continue to smile blandly as he will, and continue to dogmatize. But when I am told that fluid extract of bugleweed controls pulmonary hemorrhage, I ask what is pulmonary hemorrhage, its physiology and pathology, and, with such knowledge, how far is its artificial control possible; secondly, whether pulmonary hemorrhage does not stop of its own accord; thirdly, whether rest, diet, etc., and above all, removal of the cause is not quite sufficient; and finally, whether "mental expectancy," or "confidence," does not bring about the imperturbability that secondarily brings rest? When these questions are answered, then it is time to decide upon the virtue of the remedy proposed. Unless we have a measure of such knowledge, and experimental knowledge of the powers of the drug, a scientific conscience will not allow us to use drugs in this manner.

It has then come to this, that the value of a system of therapeutics, or of a single remedy, can only be determined when, 1, the natural history of the disease is known; 2, the influence of other factors promotive

of the natural course of the disease, as rest, diet, etc., are eliminated; 3, when the so-called personal equation of the observer is set at naught; 4, when that peculiar influence of mind on body, the hypnotic effect of extraneous conditions, the results of mental expectancy, are eliminated. That the second, third and fourth liabilities to error can scarcely be controlled is almost self-evident. Hence, for the foundation of rational or scientific therapeutics, experiment must form a basis for conclusions. Such experiment, to be of value, must imply a knowledge of the disease or the essential in the disease to be combated. Until the discovery of toxins, we had no knowledge of the entity we are called upon to counteract in diphtheria. The therapeutics of this affection, prior to the discovery of the antitoxin, was promulgated from an appalling array of data subject to extraordinary liability to error because of the possibilities already indicated and because of the limitation of our knowledge. The vast labor attendant upon the collection of data from which to draw conclusions can hardly be appreciated, but the labor is not wasted. It is true the indications for management secured are subordinated to the one principle; they are none the less valuable. Through them we learned that certain lines of diet, fresh air and sunshine, limitation of the catarrhal process, and other indications were contributive to restoration to health. Our negative information was most valuable; above all, we learned what not to do. The amount of energy expended in such therapeutic warfare, commendatory for its profusion is startling, and were it not that an atom of good always results, one would wish its course could be turned into the lines of more precisely scientific inquiry.

At too wearisome a length have I trespassed upon your time and patience. A review of the rise of therapeutics to the dignity of science shows throughout, whether in combating the old or in bringing forth the new, the naturalist, the scientist in spirit if not in fact, is the controlling force. The physician as naturalist dissipated speculative therapy; by his habit of thought and mode of action he curbed excesses, destroyed fallacies, and erected new structures. Study the downfall of any system of therapeutics, and it will be seen the naturalist made the first incursion against its folly. Study the establishment of any truth and it will be seen that the scientist laid its foundations. As in diagnosis, so in therapeutics, all advancement, all gain has been made at the hands of the scientist.

Scientific doubt first prevailed; scientific action followed. So the art of therapeutics is being replaced by the science. To establish a diagnosis, therefore, and to conduct a judicious and productive therapeutics two things are required, the scientific habit of mind and a scientific method of inquiry, the essential in the art of medicine. The steps required in the elaboration of a diagnosis have been detailed. It has been seen that patient, elaborate, precise inquiry is necessary in diagnosis, involving the expenditure of considerable time and the use of instruments of precision to attain accuracy. The same spirit must prevail in the application of remedies. The carping critic may well say some diseases are cured by remedies the action of which can not be scientifically examined. True, some therapeutics is accidental, as the discovery of the utility of sodium salicylate in the treatment of rheumatism, but that does not lessen the necessity for all to be scientific.

The enthusiastic therapist may say your reasons

will lead to nihilism. It is not necessary to be nihilistic, and indeed I am far from it. I thoroughly believe in the action of drugs. I am sure that an effect is produced, however small, by the introduction of various substances into the system. It is not that protest is raised against the non-action of drugs, but more truly doubt of the necessity for securing action is put forth, as its possibilities for good or evil can not be estimated. It is not a question whether the drugs act or do not act; it is a question of the necessity to secure such action. Save in the control of certain symptoms, for which, as pain, we have a capable armamentarium, it is not necessary to invoke remedies except those directed to the removal or counteraction of a definite cause. If the cause is not established scientifically the remedy can not be applied scientifically. But the over zealous will urge, if no drugs are administered, we lose the one great power of therapeutics—the effect of mental impression and the good results of mental expectancy. Quite true, but does the necessity of this lie exist any more in medicine than, as Zola points out, in religion?

Can not a method more practical, less harmful, or even with less possibilities of harm, be employed? The desired end is to secure faith and confidence. What can be more productive of both these than the careful, patient, systematic and analytic examination of a patient? What more surely establishes confidence than the feeling of the patient that the physician knows his ailment; that he knows how long to let it go unaided, and when to interfere with its course? Confidence, thus begot, eliminates the necessity of administering many or often any drugs, and when with the patient inquiry there is conjoined an imperturbability of spirit of the physician that he can only attain from self-confidence, secured by knowledge precisely acquired, what an amount of solace and comfort is given! Witness for yourself the therapeutic effect of one half-hour's examination of a patient. Hence it is that I plead for a scientific habit of mind in medicine. Is it not proved again that essential to the art of medicine is the science of medicine?

But do not think if we are limited in the number of drugs that cure, we have not unlimited means to restore health. The achievement of the century is that we recognize disease, not as an affection of one organ alone but as a process in which all are perturbed or involved; that, in consequence thereof, we strive to restore that perversion of the physiology of the entire economy. Hence, principles of treatment are invoked, which includes remedies and means to stimulate or repress or replace secretions or excretions, to similarly influence excess of physiologic action, to allay pain and quiet perturbed nerves. Systems of rest or of exercise, the use of water internally and externally, of heat and cold, of judicious venesection, of dietetic methods, the effect of climate, are our potent therapeutic agents.

The ultimate aim of the art of medicine is to cure the patient: It is assumed as a business, not as a calling, as was beautifully expressed in days of old. It may occur to the fledgling in medicine that he is "called upon" to engage in the professional labor, but it will soon come to him, sometimes rudely, that he is engaged in a business. It is true he has nothing to trade with; he has skill for the service of humanity. But for such service he expects remuneration. He

should have ideals of duty, but they are not different from those that any business man should hold. We may talk, we should talk, we must talk about ethics, but so should every man of business. The sooner, therefore, we remove ourselves from the pedestal we would fain usurp, and put ourselves among men, to be controlled by the ethics of all men, the better for us. Just so soon will we come into the possibility of controlling those of our brothers who do assume this practical attitude. Time was when we vied for supremacy with the judge, the minister and the school-teacher. Now the banker, the engineer, the man of science, the scientific manufacturer and organizer, in every sphere rivals us in standing in the community. That higher ethical principles and a nobler conception of duty, a firmer grasp of truth, a more inspiring stimulus to action, a sure effacement of self and selfishness can accrue from the cultivation of science, need not be maintained. Huxley and hosts of others have eloquently pleaded on these lines, far beyond the feeble powers that are given me to uphold them. We can not hide ourselves behind that self-satisfaction which attributes to ourselves qualities and virtues a little above those of the ordinary man. We must do character building on a platform similar to that applied to ordinary men. Let us arm men with truth, surround them with truth, and give them the means of seeing truth. It has been shown that there is no necessity for the therapeutic lie, that it is unscientific, as well as inconsistent. Truth only can be cultivated. The constant use of speechless, yet speaking, instruments of precision that deal only in truth, begets truth. Truth to ourselves, to our patients, truth to our fellows, truth to our profession, will silently, even unknown to ourselves, grow if scientific habits of thought are cultivated.

Assuming, then, that in the practice of our art we are engaged in establishing a business—a fact, if not acknowledged, is always tacitly assumed—it can be said as a matter of business, that the scientific habit of thought must be cultivated. It is “business” to secure the confidence of your patient, for it is a step toward getting him well. If secured by the honest method of an honest study of his ailment it is divorced entirely from quackery. The “lie,” not existing, is not paid for. It is “business” to establish truth between ourselves and our patients. Brains are necessary, but character is essential. People are far more willing to pay for character than for brains; they are far more willing to pay for honesty than for specious dogma.

The close of the nineteenth century witnesses the application to a high degree of the facts of science to the daily avocations of life. In whatsoever department of human activity we make investigation we find the application of scientific methods employed in the course of the industry. Reference has been made to the rise and progress of industry in the dawn of the nineteenth century. The close is fast approaching a consummation. In the great iron and metal industries, from mining to the conversion of the metal into its final mold, the man of science presides over its destinies. Every mine has its geologist; every furnace and every foundry its chemist; in tanning, in refining, in the making of sugar, of paints, of varnish, of oils, in dyeing, in the manufacture of cotton and woolen goods, scientific experts are employed constantly. There is no trusting to luck. Large hat-factories have chemists to pronounce upon the felt used; in

the manufacture of food-products, the knowledge of the biologist is commanded; brewing, cheese-making, and the manufacture of all dairy products can be scientifically controlled. Hansen grows and furnishes yeasts of various kinds for the many varieties of beers. Kahn has changed butter-making from an art to a science. It is needless to further multiply illustrations. Look around you; in every mill and in every factory is seen this change from an art to a science—art, so-called, is declining, science is extending.

The nineteenth century cormorant, wealth, and its coadjutant competition, have thus pushed science to the fore. The large amounts of money invested in business operations make it necessary to preclude all elements of chance.

Just as some connoisseurs aver, and others deny, that the beer of the day is not quite like the beer of the good old days of hand-brewing, so we are forced to admit that the science of medicine is not what yet may be expected of it. Science has much yet to learn from art. The change is in progress; it is irresistible; it will accrue to the benefit of mankind.

We have thus seen how, on parallel lines, art, *i. e.*, chance methods, is being replaced by science, and by the same analogies that the value of the science of medicine above the art of medicine can be appreciated. Where we have but little knowledge, the more so-called art is essential, the less precision is noticeable in our work; hence the greater the opportunities for the display of quackery; the less of the knowable, the more of charlatanism.

The history of all science and the history of medicine point to the absolute necessity for its development and growth, and its practical application to the welfare of man, that he who prosecutes it must possess a scientific habit of analysis and comparison, to put aside that which is false, recognize that which is true, or withhold judgment, as did Newton, who, when asked why he walked, replied with courage of power, “he did not know.” With the conviction that essential to the art of medicine are those qualities of heart and head that belong to him who possesses a scientific habit of mind and cultivate science in the true spirit, come new responsibilities, new hopes, new fears, new rewards, new inspirations.

Our first responsibility will be to our successors. Those of us who are teachers must change our methods. Formerly, the apprentice acquired from the master an art that required the limited training of only one or two senses. After acquiring the secrets of the art as his master divulged it, lectures were attended to hear the problems (theoretic) discussed. Now, senses must be trained—a mind developed that possesses only a scientific habit; years are required. The early labors of the college must be supplemented by labor in the medical school. Two years should be devoted to the study of anatomy, including histology and embryology, to physiology, including as much biology as possible, to medical chemistry and to pathology. We owe it to our profession and to our students. We have added a year to our medical curriculum and robbed the college course of its valued year. We must replace it by honest training. The laboratory and the hospital-ward are to be the student's theater of action. Didactic lectures are to be the exception rather than the rule. In this manner, and in this manner only, can the student be fitted for his life-duties. Our further duty is toward the noble charities placed under our guidance. We cry against hospital abuse and dis-

pensary injustice. Need we not look to ourselves? Do we conduct our labors in such institutions in accordance with modern scientific methods whereby we contribute to knowledge and human health? Pardon a passing thought. All such institutions should be under the guidance of a State board, similar to the State Board in Pennsylvania controlling lunatic asylums. Undoubtedly abuse creeps in on the side of the management as well as the physicians. Then, if dispensaries are conducted on scientific methods there would be room for every man who deserved a position in a dispensary—certainly in the dispensaries of Philadelphia. Time will not permit further extension of this thought. The fact is, our methods must be reformed in our dispensary as well as in our hospital work. It is unjust alike to science and to the public to see as many as twenty-five patients per hour in dispensary practice.

Our fear is the possibility that we may become practical in the sense that the politician has grown practical. In this stage of our evolution such fears can be awakened. The ophthalmologist is our most scientific man; we know the dangers that surround him, but we see him emerge unscathed from the ordeal. Moreover, the environment of the physician is such as to preclude the possibility of the development of any but the higher and nobler traits of character.

The truths of medical science and their practical application are cosmopolitan. Law is limited by political barrier; religion by race and by mental development. The promulgation of truths in medicine, or the establishment of a method of its art, affects for good the entire universe, and not only men but all animal creation. The labors of Mitchell on snake poisoning, in Philadelphia, touch the welfare of the entire population of India. The result of Lister's researches are as valuable in China as in England. The words of Koch are as powerful in Japan as in Berlin. What greater reward is it than to be an humble fellow worker in a field so broad, and what higher inspiration than the stimulus attending such labors.

Our hope is that with such necessity for scientific labor will come the greater development of truth and character. Cant and hypocrisy, quackery and deceit, can not thrive in such an atmosphere, and as the years of toil are added one to the other, character grows broad, firm, clear. Constant association with instruments of precision that can not lie, incites truth. With the attainment of scientific habits, what more glorious rewards can come than that which accrues from the noble purpose, the lofty aim, the chivalrous spirit of the man of science.

Let us then, be not impatient. The adamant position secured by the labors of Lister and Koch and Pasteur; the advanced state of preventive medicine at this day; the scientific method of the treatment of disease, as seen in that of diphtheria; the vistas that are opening with the advent of organ-therapy shows the rise of a new science of medicine. Unfortunate only are we, that to witness the dawn only, is our privilege. Of what the high noontide of medicine will show we can but hear the whisperings.

Sal Ammoniac in Tropical Dysentery has been found effective by Attygalle (Ceylon), administered every four hours, combined in some cases with small amounts of opium and cannabis indica. The blood disappeared from the discharges and the colics ceased by the third or fourth day in nearly every case. — *Semaine Méd.*, May 11.

SOME DISORDERS OF DIGESTION OF FREQUENT OCCURRENCE.

Read before the Medical Society of Erie County.

BY J. H. MONTGOMERY, A.B., M.D.

ERIE, PA.

Probably there is no complaint more frequently encountered in practice than disordered digestion. It is seen at all seasons, at all ages, and in all ranks of life. This paper will attempt to describe in outline the class of cases we see almost daily, and which are frequently spoken of as "functional disorders of digestion." By this is meant an abnormal condition of function unaccompanied by any pronounced anatomic change in structure, so far as we know. This limits the scope of the paper, as it excludes all those forms of disordered digestion resulting from organic disease of the alimentary tract, or any other part of the body, also the very acute forms, often called cholera morbus, and the indigestion of very young children. The rarer forms manifested by various reflex symptoms will not be considered.

The simplest method of describing the class of cases treated in this paper is to relate the average history and symptoms given by a patient applying for relief: The patient usually begins with the statement, "my stomach must be out of order," or "I am sick at my stomach all the time," or "everything I eat seems to sour on my stomach." Sometimes there is a complaint of epigastric pain. This is about all the patient volunteers as to the nature, or description of the disorder, but questioning at once elicits other significant symptoms. There is apt to be an eructation of gas with or without a bitter sour taste after the ingestion of food, accompanied by epigastric distress relieved by the belching of gas. The above phenomena are often attended with precordial pain and oppression extending across the left chest and a variable distance down the left arm, shortness of breath, worse on exertion; in other words, the group of symptoms described as palpitation of the heart. Sometimes there is a slight feeling of uneasiness in the head, but never amounting to headache, also a feeling of languor, though not pronounced. The tongue is inclined to be coated presenting rather a brownish appearance, with the accompanying disagreeable taste. Vomiting is rare in the cases under consideration, though nausea is met with in a few cases. Usually the bowels are undisturbed; diarrhea does not occur in this form of digestive disturbance.

There is another class of cases more common than the one just mentioned, and the variety, in my experience, is the more frequent. These patients always begin their complaint with, "I am all used up," or "I am good for nothing and don't know what the matter can be," or again "I must be bilious," or "My liver must be out of order," and most frequently is the assertion made "I must have malaria from the way I feel." Complaint is made of the desire to sleep most of the time and inability to attend to customary duties without great mental effort. Further questioning brings out the statement that the languid feeling is always present and that sleep brings no sense of refreshment, the patient often feeling worse after sleeping. There is very apt to be a change in the disposition, the individual becoming irritable and trivial affairs cause much worry. There is often an

inability to fix the mind on anything for more than a few seconds consecutively, and even the reading of the daily paper becomes an effort. The one prevailing desire is to be let entirely alone in every respect, and could the inclination be followed, the patient would be content to remain sitting quietly gazing into space and the mind thinking of as near nothing as possible.

When local symptoms are sought, usually there is found a sense of fullness in the abdomen, most pronounced three or four hours after a meal, and sometimes a sense of gas in the intestines, which may be audible. In a few cases there is a feeling of weight or uneasiness in the right hypochondrium, and even tenderness will be found. The tongue is usually clean, though in a few cases there will be a complaint of disturbed taste, and with this is often seen a brownish coating. The bowels have a tendency to be lax, moving two or three times a day, with the passage of more gas than is usual. The movements often smell so fetid that the attention of the patient is drawn to this fact. In a few cases of long standing, or that are especially marked, there is an abundant precipitation of the amorphous urates in the urine. This symptom is often the first to lead the patient to seek medical advice. The appetite remains unchanged usually and there seems to be no sort of food that the patient notices that aggravates the symptoms. The temperature is normal, the pulse usually accelerated a few beats and with less tension than in health. A few cases show a brownish hue of skin, which is different from a jaundiced skin. Palpitation of the heart is quite common in these cases. Sometimes diarrhea is the only symptom complained of by the patient.

The line between these two forms of digestive disorder is by no means very sharply drawn, one often merging into the other, and two often co-exist.

In seeking the cause in any case we usually find that one of the following is the active factor: Deficient teeth; rapid eating; improper food; use of tea, especially strong tea; eating between meals; eating when fatigued; too severe exercise after eating; use of alcohol, especially if concentrated, and most marked if taken just before or after a meal. Frequently two or more of these factors will be found to contribute to the production of the disorder. I have not enumerated them in their order of frequency, or their importance. Such a course is an impossibility.

To fully understand and appreciate the changes occurring in these cases a brief résumé of the process of normal physiologic digestion, and tracing the changes from the normal when the above mentioned causes operate, the production of the symptoms, both subjective and objective, will assist in understanding how such symptoms are produced, and the indications for the proper treatment become apparent and readily met. The first step in the digestive process is the mastication of food, the moistening and mixture with saliva and the oral mucus. This step requires the presence of proper teeth, the molars, both in the upper and lower jaw, and grinding one on the other. Simultaneously the food becomes mixed with and moistened by the saliva and oral mucus, and further moistened by the pharyngeal mucus in the act of deglutition. The saliva has slight amylolytic properties, but it is not likely that the brief sojourn of the carbohydrates in the mouth is sufficient to permit any transformation of importance, and if such a change did occur it would be promptly stopped by the acid of the gastric

juice. Doubtless the chief function of the saliva is to moisten the food, rendering deglutition easy, and after thorough mastication the moisture more readily penetrates the substance of whatever may have been submitted to the action of the teeth. Even the softer forms of food, as bread, mashed potatoes, etc., are submitted to the same process, or should be in healthy digestion.

So far the digestive process has been merely preparatory for the important chemic process to begin in the stomach. The gastric secretion we may consider to be composed of hydrochloric acid, pepsin and rennin, of which the acid seems to be the important ingredient, at least from the standpoint of this paper. The action of the gastric juice is mainly proteolytic. Any other action may be disregarded. The proteids are transformed into peptones after passing through two or three preliminary stages. In undergoing this change they apparently swell up and gradually liquefy. The muscular movements of the stomach play an important part, inasmuch as they serve to mix the gastric contents thoroughly by a churning process, and eventually to force them into the duodenum for further digestion.

The peptones are by no means absorbed from the stomach, nor in fact are liquids absorbed to the extent formerly believed. It would seem that the stomach digestion is only an additional preparatory step in the digestive process. There is reason to believe that if the stomach fails to do its share of the transforming process properly, either from any inherent fault or some preceding failure of the digestive tract, viz., the proper mastication, that products incompletely prepared pass into the intestine, thus putting extra work on the intestinal part of digestion, and thus apt to embarrass the latter in the performance of its allotted function. The ingested food, partly transformed, now reaches the duodenum, where it is mingled with the secretion of the pancreas and liver, and the great chemic process of digestion is in the last stage.

As for the pancreatic secretion and the bile, and the part they play in the digestive or chemic process, suffice it to say that the secretion of the pancreas has a decided effect on the proteids, starches and fats. It is on the two latter that it seems to act principally, converting the carbohydrates into dextrose, which is absorbed by the circulation; the fats are emulsified and the proteids dissolved. The solution of the proteids is accomplished in a manner different from in the stomach. The proteids in the intestine disappear by a process of erosion instead of liquefaction.

After these chemic changes most of the converted food is absorbed by the circulation and the lacteals, the grosser and indigestible portion passing into the colon and after absorption of the moisture, forms the body of the feces. The digestive cycle is now completed, and the various structures engaged are entitled to a rest until the following ingestion of food.

The entire alimentary tract, from the lips to the anus, is the home of various forms of bacteria, including those causing putrefaction and fermentation. The ingested food, even if previously sterile, gathers a supply in the mouth, gains more in the stomach, and then meets a larger army in the small intestine.

That the bacteria of putrefaction do not always have full sway and increase seems perhaps remarkable, and they would were it not for a certain inhibitory influence. In the mouth the food remains too short a time to permit their growth. In the stomach

the presence of the hydrochloric acid acts as a restraint. In the small intestine it is known that the contents have an acid reaction, due to the presence of acetic acid, which probably is the result of certain bacteria developing normally in the carbohydrates with the production of this acid, which serves the purpose of restraining the action of the putrefactive bacteria on the intestinal proteids. In the colon it is the province of certain bacteria to develop and form the resulting products, but these need not attract our attention just now.

Briefly then this is the condition found in normal digestion, and it is evident that each portion of the digestive tract must do its share of the work or some one or more portions are apt to be overworked. As a result the overworked portions are apt to be unable to perform their function properly, and soon there is further impairment of the digestive function.

How such an impairment is produced and just how the above mentioned causes of digestive disturbances play their part or parts, will now be traced in detail.

Deficient teeth and rapid eating both act in the same manner. The lack of teeth does not permit the food to be properly divided and mixed with the saliva while in the mouth, consequently the mass reaches the stomach in an imperfectly prepared condition, sometimes insufficiently moistened. The stomach then has to do a portion of the work belonging to the mouth, and work it is unfitted to perform. It can not divide the food properly, and in the place of finely divided and moistened masses that can be readily acted on by the gastric juice, it has to work on the larger masses which can not be thoroughly permeated by the gastric secretion. The proteid portions of the food can not be liquefied readily and have to pass into the intestine in a preliminary stage to the peptone. The food not being thoroughly permeated by the gastric juice and containing bacteria derived from the mouth, is in a favorable condition to undergo decomposition, and this is exactly what does occur, and the resulting production of gas, fatty acids and various organic compounds of the ptomain type. The epigastric distress, the eructations of gas, the feeling of nausea naturally result from such a condition.

Improper food acts in a similar manner, and by improper food is meant not only quality but quantity. Too much food of a bulky and insoluble kind, even if properly prepared in the mouth, can not be properly cared for in the stomach and goes through the same or similar process of decomposition as just described. Among the improper foods may be considered a great excess of any one variety, such as too much bread, too much milk; commonly, nuts, dried vegetables, heavy pastry, cooked shell-fish are the varieties that are apt to cause trouble. Strong tea, from the tannin contained, interferes directly with the chemic process of digestion. The proteids fail to be transformed in the presence of tannin, and peptones already formed are precipitated in an insoluble form. There is one class of patients that owe all their trouble to the tea habit—sewing women. They commonly use very strong tea as a stimulant and keep a pot of the liquid on the stove, resorting to the drink frequently. This class of patients state that all the desire for food they have is for tea and toast, and they show by their appearance that such is the case.

The habit of eating between meals is a cause of difficult digestion, inasmuch as the stomach in place of having a period of rest is compelled to perform its

function all the time, consequently it, like every other organ of the body when overworked, fails to perform its duty properly. The food taken between the regular meals, and after a time the proper meals, undergo the decomposition before described.

Eating when fatigued and exercise too soon after eating cause disordered digestion in a somewhat different manner at first, and later in the same way as the causes enumerated. When the body is fatigued from any exertion, either physical or mental, the entire system is in the same condition and the digestive system is unable to do its work from lack of strength. Exercise too soon after eating produces trouble from the fact that the energy or force required by the process of digestion is diverted to another purpose, leaving insufficient to take proper care of the food. There is a great deal of truth in the old saying, "Too tired to eat." When the system is fatigued the food fails to digest and undergoes the same chemic changes found in other conditions.

So far the changes occurring in abnormal gastric digestion have alone been mentioned. The most important changes occur in the small intestine when the improperly prepared food passes into it from the stomach. The intestine not only has its ordinary duty to perform, but is compelled to what was left unfinished by the preceding part of the digestive tract. Fortunately nature is very indulgent and will tolerate this sort of thing for a considerable time, but finally the intestine becomes unable to attend to the increased demand and even fails to perform its natural work properly. In the intestine is found all three classes of food, proteids, carbohydrates, fats. The proteids have not been properly cared for in the stomach and now demand work from the intestine, which it gives but at the expense of allowing the two other classes to suffer. The proteids may already be filled with bacteria and gather more in their new domicile. The carbohydrates are improperly cared for and their normal decomposition with the production of acetic acid, which we have seen prevents the proteids decomposing, becomes abnormal and perverted, and other products are formed. The proteids decompose from lack of proper inhibitory influence, with the resulting formation of abnormal products, many of which are powerful systemic poisons, and various gases. The fats likewise fail to be properly cared for and in place of their undergoing normal emulsification they are decomposed into fatty acids, the various sorts of gases and poisonous products. The intestine has become an active poison factory instead of digesting the food normally, and produces gas in sufficient quantities to cause pain from distension, and the imperfectly digested food is a foreign body to the intestine and is hurried along to the colon and discharged in unnatural stools, in which the undigested food can often be recognized.

The poisonous compounds formed are of the greatest interest to us, as they are to blame for all the constitutional symptoms encountered in cases of imperfect digestion. Their chemistry is complex and just beginning to be understood. They are described in a general way as toxins. These are absorbed and produce a condition of sepsis in most instances, as indicated by the soft and increased rapidity of the pulse. Some cause elevation of the temperature as well and various disturbances of the entire system can be attributed to their presence in the blood. There are some of these poisons that can be detected in the

excretions, chief of which are indol, indican, leucin, tyrosin, etc. Besides, the potassium and ammonium salts are freed and absorbed, producing their effects. These poisonous products produce the languor which is nothing more than a septic condition in these cases. The gas produces the distension, which is increased by the splitting up of the fatty acids, and is often expelled from the stomach or remains in the bowels manifesting its presence by distension and pain, and frequent rumbling, and finally escapes per rectum. This same pressure causes palpitation of the heart in many cases, though this latter symptom is the direct result of irritation of the vagus by the abnormal food products in the stomach. The carbohydrates also form their share of gas and acids. The undigested food irritates the intestine, often causing diarrhea with or without sharp colicky pains.

COURSE OF TREATMENT.

I do not wish it to be understood that the two forms of digestive trouble are all that we meet with in practice, for such is not the case, but they are by far the most common. Furthermore, it is not at all a simple matter to draw the line clearly between the two, for the one having prominent gastric symptoms soon runs into the other type. Often patients are seen with the typic symptoms of both forms. If left untreated and the same habits are continued by the patient, the complaint may be prolonged indefinitely, but this is not of frequent occurrence. The human digestive system will stand an enormous amount of abuse for a long time, and then will do its work kindly, if given a chance. I do not recall a single case that had apparently undergone any permanent anatomic change, and none that could not be relieved if the active factors, as previously enumerated, could be removed and the directions followed. Such a result is possible in every case, and I know of no complaint that gives such a gratifying result when properly treated.

The treatment is mostly dietetic; medicine is only an aid for a short time, to endeavor to overcome the faulty digestion then existing. The first and most important step is to remove the cause, or the causes, as two or more may exist. Lack of teeth, especially the molars, can be removed by artificial teeth, and modern dentistry has given us bridge work which is free from the objections belonging to plates, and is many times more serviceable, especially in the lower jaw. All patients with dyspeptic troubles are better without tea, and its use should be stopped. Rapid eating is not readily stopped, but with patience the sufferer succeeds. Eating when fatigued can be avoided, and rest in the recumbent position for ten or fifteen minutes before a meal is sufficient. No exercise should be taken for at least an hour after eating. This does not prohibit the usual walk to and from business, but means anything like hard work, long walks, riding a wheel, or even severe mental exertion. Exact directions are required for each case and differ in each case.

Improper food is more difficult to describe. I can only state that by improper food is meant that variety that is apt to readily ferment or to decompose in a healthy digestion, and is all the more likely to do so in the cases under consideration. Improper food may be divided into two classes for our purpose. The first class consists of those articles containing a large amount of cellulose, such as the coarser vegetables,

skins of fruit, etc. Also those containing an excess of fat, or prepared with the aid of fat, such as all fried food, made dishes, gravies, and in a general way those articles of food that merely gratify the palate without having any decided nutritive value. Sweets of all sorts are especially bad from the starchy matter contained, and especially from the pernicious habit of taking them between the meals. Oatmeal or other cereals as commonly eaten, the first thing in the morning, are especially injurious, not *per se*, but from the sugar used to render them more palatable. Sweets of any sort taken the first thing at a meal, or a short time before a meal, will effectually destroy the appetite. It is just as reasonable to begin the morning meal with a cereal flavored with sugar and cream as it would be to begin the midday meal with cornstarch with sugar and cream. It is quite probable that the starchy or sweet foods taken in this manner undergo rapid fermentation in the stomach owing to the insufficient secretion of gastric juice, and the resulting exercise of the inhibitory influence of the hydrochloric acid on the bacteria fermentation. At any rate it is a matter of common experience that cereals taken after meal do not cause the same disturbance. I frequently find patients who say, "all I care for at breakfast is a dish of oatmeal and a cup of coffee." Yet these same patients find that if the oatmeal is taken as a dessert, that is, after eating other food, there is a good appetite for other varieties of food and enjoyment left for the cereal without any of the subsequent discomfort. This serves to illustrate how a proper food may become an improper one, owing to the time of a meal it is taken.

Observation for some time has led me to notice there is one class of our population that is especially apt to suffer from digestive disorders, the farming class. This opinion has been frequently corroborated by men accustomed to see more of this class than I. I have inquired about the digestion of this class for a number of years and find that the majority of their minor ailments are digestive disorders. The cause of this is not the occupation but the food, which I think may be called decidedly improper. It is customary to find the three daily meals in many farmhouses to consist of salt or fresh pork, usually fried, fried potatoes, strong tea, sweets in the form of canned or preserved fruits or honey, and usually a liberal supply of pancakes with the ever present supply of maple syrup. Rapid eating is also the custom, and many of the older people lack the teeth necessary for proper mastication. Add to this fact that as soon as the meal is finished work is at once commenced, while the horses are having the necessary rest, and is it any wonder that digestion should be impaired? The fact that all do not suffer shows how much abuse our digestive system will tolerate before rebelling. I do not intend to cast any slur on the farmers as a class, but make use of a description of the custom of many of them to describe how improper food plays such an important factor in producing imperfect digestion.

There are two other classes of people that suffer from two factors at least in causing their trouble, improper food and eating between meals. One class consists mainly of students, principally girls, who are very fond of eating after study hours are over for the day, and that is usually late in the afternoon, at a time when the stomach and intestine can not get rid of the ingested food before the next meal when it is called upon to perform its function without any rest. The

food taken by these patients is decidedly improper consisting usually of pastry of some sort seasoned with preserves and followed by candy, or the latter is often taken on the way home as an appetizer for the coming repast. The lunch soon becomes the regular meal and a forced attempt to take food at the proper hour fails, or results in the production of trouble which increases as long as these habits are continued. Is it any wonder that the appetite grows poor, that flesh and strength is lost, and the parents become worried? Nearly two years ago I read before this society a paper on the subject of anemia in women occurring at an age of 10 to 20 years. At that time I spoke of the affect improper food and carelessness in eating had in producing an anemic condition. Further experience only more fully strengthens my belief that many anemic cases are due to this habit almost entirely. The other class referred to are molders. These men usually have a lunch about 10 A.M., with it a liberal allowance of beer and at the mid-day meal there is no appetite and more beer is taken to sustain the strength, another lunch in the middle of the afternoon with beer, and the evening meal is taken with the same enjoyment as the noon meal. Any proper amount of food taken at the regular meals usually causes distress. These two classes evidently keep their digestive system at work all the time except during sleep, and probably many of them do at that time; that it fails to do its work under such conditions is not surprising.

The effect of concentrated alcohol on digestion is too well known to require any description beyond the fact that it interferes chemically with gastric digestion; besides it affects the liver seriously in its work.

The description of these various classes of cases may assist in showing how the several factors contribute to cause trouble, and bearing them in mind the indication for the dietetic management of any case becomes evident. Briefly, this indication may be stated to be a correction of the patient's bad habits in eating, the direction as to the proper sort of food, the proper time for eating, etc.

Medicinal treatment is only secondary to the dietetic management, and without the former our treatment by drugs is practically useless. Many patients are benefited by taking a glass of water a short time before meals, especially on rising in the morning. This seems to have a good effect in causing the stomach to contract and expell any mucus or remains of a former meal, and so be better prepared to care for the food soon to come. Whether the water be hot or cold seems immaterial, and as cold water can always be obtained, I usually direct that the cold be taken.

Hydrochloric acid in the dilute form is of great value in cases with gastric symptoms, either alone in doses of 10 to 20 drops, or combined with two or three drops of liquor arsenii chloridi of the pharmacopeia. The purpose of the dilute acid is merely to prevent any decomposition of the food in the stomach, which I think it does, as naturally it is this same acid that exercises an inhibitory influence on the bacteria. The arsenic seems to assist in this action. I have not used any pepsin preparation for some time in connection with the acid, as it seemed superfluous, the acid being given for a definite purpose. If fermentation or decomposition of food continues, or is excessive, the salicylates are useful in addition to the acid. The use of the various so-called vegetable digestives has always seemed to me an illogical practice, and I have

never noticed any benefit from their use. Calomel in minute doses once or twice daily is useful, principally for the stimulating effect on the liver. The use of alkalies for the arrest of the gas and the resulting distention is decidedly an improper thing as a routine measure. It will neutralize the formation of fatty acids with their eructation by forming a chemic combination with these acids, and at the same time it forms a combination with the hydrochloric acid and thus aggravated the symptom for which it was given. An alkali before meals has a different effect, though I have never found any benefit from such use. I have seen a number of cases that were aggravated by the continual use of alkalies to relieve the acidity of the stomach. It is a far more rational proceeding to prevent the formation of gas than it is to allow it to form and then administer a remedy that alleviates apparently the trouble but all the time is aggravating it. The use of the muriatic acid, with or without the arsenic or salicylates, will do far more for this condition than all the alkalies a patient can swallow while digestion is going on in the stomach.

When the symptoms are mostly of intestinal origin, a different method is apt to give better results. It is necessary that the stomach do its proper share of the work, and by the time the intestine begins to fail in its work the patient has begun to allow the stomach to have a chance to do its work, by taking less food, either from a diminished appetite, or from noting there is less epigastric distress following the ingestion of the smaller quantity. Before any success can be secured in the faulty digestion of the intestine it is essential that the preceding portion of the alimentary tract be in proper working order. Fortunately this is the case generally, as just stated; if not, the proper directions as to diet, medicine, etc., must be given.

Calomel in small doses once or twice daily is of decided value; it increases the hepatic secretion, perhaps the pancreatic, but it is doubtful if it can have any antiseptic effect in doses of one-twentieth to one-tenth grain. Dilute nitric or nitro-muriatic acid in 15 drop doses are very useful, they act through their effect on the liver, probably like calomel. Phosphate of soda sometimes acts well given in teaspoonful doses three times daily at first; later only before breakfast. The pancreatic extract proves valuable, especially in those cases accompanied by much gas in the intestine, given in doses of 3 to 6 grains an hour after meals. Inspissated ox-gall can be given with it if desired. The palpitation of the heart is often an annoying symptom and due to gas in the gut pressing on the heart. A ready and sure method of alleviating it is with nitroglycerin one-hundredth grain every half hour until relieved, one dose is usually sufficient and produces comfort in ten minutes. Diarrhea, if present, is to be treated as the digestive disorder and not by itself with laxatives or astringents. In cases weakened by the continued malnutrition, alcohol is often given with the result of an improvement in the general welfare. The best form is a dry wine well diluted with a carbonated water, or whisky and brandy well diluted. Sweet wines and malt liquors always produce more gas and the resulting discomfort. The above plan of treatment is the one I have employed for some years and invariably gives good results, but after all it should be remembered that it is only my personal experience and is open to discussion.

115 West Eighth Street.

CEREBRO-SPINAL MENINGITIS, WITH REPORT OF CASES.

BY J. F. SHELLEY, M.D.

ELMDALE, KAN.

The disease has been demonstrated bacteriologically to appear in epidemic and sporadic form. In sporadic cases it is difficult and frequently impossible, if severe and rapidly fatal, to differentiate this form of meningitis from that secondary to other infectious diseases, except by lumbar puncture, and therefore it is as yet impossible to say how extensively the disease exists in sporadic form.

In 1880 Eberth supposed he had found in the micrococcus lanceolatus the essential cause of the disease, and since then until about 1895 it was generally accepted as the specific cause, the demonstration of a distinct micro-organism in 1887 by Weichselbaum, which he called the "diplococcus intracellularis meningitidis" notwithstanding. It seems that the organism found by Weichselbaum was supposed to be the lanceolatus (Flexner and Barker, *Am. J. Med. Sciences*, Vol. 107, p. 159), and it was not until Jaeger, Heubner and Finkelstein about nine years later took up the matter and confirmed the demonstrations of Weichselbaum that the meningococcus of Weichselbaum received general recognition. These investigators clearly differentiated between the two organisms both microscopically and by inoculation experiment. They found the lanceolatus far more virulent than the intracellularis.

Recently the epidemic in Boston through the researches of W. T. Councilman, Mallory and Wright (*Amr. Jour. Med. Sciences*, March, 1898), has thrown much light on the etiology of the disease, and has given us a clear definition of all the aspects of the micrococcus both in the organism and in culture. They made lumbar puncture in fifty-five cases and demonstrated the diplococci in thirty-eight of them. They think the negative results in the balance of the cases were not always because they were not present, and some of the punctures were made presumably after they had disappeared from the fluid.

In general he confirmed the results of Weichselbaum and Jaeger, but he thinks the capsule referred to by Jaeger as occasionally met with is simply a swollen condition in which the organism would not take the stain, except a small portion of the center. Councilman also confirms the statement of Weichselbaum that the diplococcus is decolorized by the Gram method, while Jaeger said coverslips could be stained with the Gram method. There seems to be some difficulty to differentiate between gonococci and the diplococcus intracellularis, but the latter vary more than the former in size and the meningococci are said to grow well on glycerin-agar.

The mode of entry and the avenue are still matters of very uncertain speculation. The nose, the ear and the intestinal canal all have been supposed by various observers to be the infection atrium. Strümpell believed there was a relation between coryza and epidemic meningitis, and if this be true, with the fact that Sternberg found the micrococcus lanceolatus in the saliva of 50 per cent. of healthy individuals, it was not hard to believe so long as this organism was supposed to be the cause of the disease, that the nares served a very probable way of infection. That the real microbe of the disease is not so constantly found in these parts does not, however, bar

the possibility of thus infecting the meninges. Weigert made note of purulent inflammations of the nasal sinuses accompanying the disease. The writer has also seen a case (noted below) in which there was a copious discharge of purulent matter from the nose. But Flexner and Barker in their autopsies of acute cases at Lonaconing found the nasal sinuses free from disease. They believed the alimentary tract to be the source of infection. But it may be noted that they at that time still attributed the disease to the micrococcus lanceolatus.

The source of the infection outside of the body is likewise a matter shrouded in obscurity. We know that it is likely to manifest itself in overcrowded, ill-kept quarters. That it is most frequent during winter and spring, and that sudden lowering of temperature especially in wet weather is generally during an epidemic accompanied or followed immediately by the appearance of new cases. These are questions that will probably be explained in the future, but at present they are only suggestive.

There is as yet no evidence to prove the disease contagious. Inoculation experiments since the isolation of the diplococcus intracellularis and its distinction from the pneumococcus have been mainly negative, except when introduced into the pleura or the meninges. If inoculated into the latter a typical meningitis is the result and in the pleura it causes a pleuritis.

The disease is distinctive in that it is essentially primary, while other forms of meningitis are generally secondary to disease located elsewhere, or they are caused by injury in which the seat of infection is made to communicate with external parts. Councilman says, "in tuberculous meningitis we have never found a single case in which the lesion in the meninges could be regarded as primary. The only two cases of apparently primary infection were in the two pneumococcus cases noted, and in one of these the infection may have come from the intestinal canal."

The symptoms are varied in extent and intensity. The onset is usually abrupt and agonizing. Without premonition, the patient is seized with violent pains in the head and back, chill, fever and vomiting. In the severer cases these symptoms, with extreme restlessness, merge into active delirium and spasm, and death may take place in a few hours or days.

The headache is a prominent symptom throughout the course of the disease. It may be general or localized, but is apt to be most marked in the frontal and occipital regions. It may be continuous with acute exacerbations, or it may remit only to assert itself at intervals of various length. It sometimes recurs with striking regularity, but at other times there is no regularity whatever to the returns. Light to the eyes increases the pain in the head, and pains the eyes. The pain in the back is equally intense, and has the same characteristics. It soon extends to the spinal nerve-roots and to the nerves themselves, and motion becomes very painful. Hyperesthesia is soon marked in localized places or it may be general. Some authors mention anesthesia. I have not noted this symptom but can easily see why the exudate should produce it. The pain of meningitis is apt to be of a sharp lancinating character.

Temperature is generally moderate and bears no special relation to the severity of the disease. It may

be subnormal, or in approaching dissolution may reach a very high degree. There is no regular course of fever in meningitis as in typhoid.

Usually vomiting does not continue beyond twenty-four hours, but may be a prominent symptom throughout the course of the disease. More often it is recurrent. The cause of the early vomiting is central, but later, when the secretions are much disturbed, it may be partially due to indigestion. The tongue, slightly coated in mild cases, soon becomes heavily covered with a dark to brown coat, and presents a dry and cracked appearance in the so-called typhoid cases. The mouth is not infrequently covered with sordes. A characteristic feature of the disease is the retracted abdomen, but this condition may be changed in those cases of severe grade with prominent digestive symptoms, and in which intestinal secretions are greatly modified. It is not uncommon to find the abdomen tender, but this is due to the hyperesthesia general over the body, and must not be mistaken for the tenderness of ulcerated intestinal glands. The early history, the absence of the typhoid eruption, want of gurgling in the iliac fossa, and tenderness extending over the entire abdomen, rather than its localization in the iliac region, will usually serve to differentiate it from typhoid.

The pulse is variable and may be very rapid and feeble or it may be fairly hard and slow. It is frequently intermittent, dicrotic and irregular. It may be very rapid at first and then become abnormally slow, or the reverse may be true. It often changes in the same case and bears no relation to the temperature range.

Respiration is usually slightly increased in frequency in cases not complicated with pneumonia, and when so complicated, or in congestion of the lungs, it is increased in proportion to the lung affection. It may be Cheyne-Stokes in character, more especially in cases complicated with albuminuria. Involvement of the nerves of respiration may cause the most painful dyspnea. This may also be caused by disturbed innervation of the larynx. Sighing respiration is also noted.

The most constant form of eruption is the herpetic, and appears about the face and neck. The lips are mostly affected. A petechial eruption on the body or limbs is not quite so common, but is perhaps more characteristic of the disease. Other changes are noted in the skin, at times. The eruption bears no relation to the severity of the other symptoms and it may be absent in the severest cases.

The urine varies from scanty secretion with high specific gravity to polyuria with specific gravity 1002 to 1005. It is frequently alkaline and deposits excess of phosphates. The triple phosphates are especially abundant. Albuminuria is not an infrequent complication and should be constantly looked for. One of the author's cases had vesical paralysis; also paralysis of the sphincter ani.

The bowels are constipated, with very few exceptions. There are, perhaps, more exceptions among children than adults. Flexner and Barker report four cases in the Lonaeconing epidemic, which were complicated with dysentery, and which they made the subject of special study. The discharges contained mucus, pus and blood, and the predominating organism was a lancet-shaped coccus, in pairs, apparently encapsulated. They also found bacilli resembling the coli communis, and short chains of streptococci. One of the

author's lighter cases was dysenteric, with mucous pus and blood presenting.

Motor and sensory disturbances are a general part of the disease. Vision is disturbed in many cases, and metastatic optic neuritis is not uncommon. Strabismus and nystagmus are common. Sense of taste and smell may be perverted and hearing lost. The latter may, however, be due to suppurative inflammation of the middle ear, as well as to sensory disturbances. Muscular contraction soon manifests itself and we have the retracted head, opisthotonos, orthotonos (Osler), the arms flexed on the chest, the thighs flexed on the abdomen and the legs on the thighs. In this condition the case presents a typical picture.

Flexner and Barker in their report, and Osler, in "Nervous Diseases," edited by Dercum, cite a symptom described by Kernig as pathognomonic of the disease. It is what they call flexion-contracture (called by Kernig, beuge-kontraktur), by which is meant an inability to extend the leg while the thigh was flexed on the abdomen, or at right angles to it, this inability to extend the leg disappearing as the thigh is extended. I am surprised that, in consideration of the hyperemic and inflammatory condition of the nerves and nerve-roots and consequent hyperesthesia, it did not occur to them that this was due to tension on the sciatic nerve and that the same condition obtains in other painful affections of this nerve, as in sciatica neuritis. However, it may serve an important office in differentiating joint complications of the disease from nerve pain, as it differentiates hip-joint disease from sciatica. Epistaxis is a common symptom.

Typical cases not of the severest type are easily recognized after a few days. On the other hand, great difficulty may be experienced very early in the disease, and especially in severe sporadic cases. Malignant scarlatina, in which death occurs before the eruption appears, can be distinguished only by the history of the contagion. The writer has had two such cases, one of which gave no history of contagion, but three others in the same family following immediately with scarlatina, gave evidence for the diagnosis. The other was a child of 3 years in a family in which three older brothers had scarlatina and were convalescing. Without premonition it was suddenly attacked with vomiting, and this was followed immediately by convulsions, the eyes set, teeth tightly closed (trismus), the head drawn back, the back in opisthotonos and frothing at the mouth; soon becoming comatose, it died in about six hours after the first symptoms. Involvement of the nerve centers in the course of other infectious diseases, as diphtheria, pneumonia, typhoid, etc., can usually be differentiated by the symptoms of the primary disease. We think there is no longer any doubt that those cases of the acute infections which manifest the central symptoms are cases of involvement of the nerve centers proper. When we say central symptoms, we do not mean the ordinary delirium of typhoid, nor the coma of uremia. Postmortems in typhoid with central symptoms have revealed the specific typhoid bacillus in the meninges (Ohlmacher, JOURNAL AMERICAN MEDICAL ASSOCIATION, Vol. 29, p. 419), likewise the micrococcus lanceolatus in meningitis complicating pneumonia. Councilman found, besides the diplococcus intracellularis, the tubercle bacillus, pneumococcus, streptococcus, bacillus pyocyaneus, staphylococcus pyogenes aureus and the anthrax bacillus.

Tuberculous meningitis is recognized by its insidious and gradual development.

Where two or more members of a family are simultaneously attacked, as in the recent cases of the writer, it is easily mistaken for acute poisoning.

In differentiating meningitis, the fact that a case recovers may have an important significance. Councilman says, "We believe that all infections of the meninges, other than the *diplococcus intracellularis*, are fatal." The one most important means of differentiating, however, is the examination of the exudate obtained by lumbar puncture, both with the microscope and in culture experiment. Lumbar puncture is said to be made not only with impunity, but in some cases with actual benefit to the patient (Councilman).

Medical treatment, for the main part, aims at the comfort of the patient and the relief of complications as they arise. He should be placed in a large, well ventilated room and the light modified to his comfort. The diet should be liberal and nutritious, milk in quantity being best suited to most cases. Opium in some form is indicated. It relieves pain, quiets the nervous system, lowers the pulse and increases its volume, and frequently lowers the temperature, thus making it possible to better nourish the patient. Bromids are important adjuvants to morphin or other opiates. An important matter in the administration of opiates is to give them cautiously, but increase until the desired effect is produced. They increase the desire for food. To move the bowels, I prefer calomel in small and divided doses, generally 0.065 gram in quarters or sixths; this may be given, when necessary, throughout the course of the disease. These fractions are given every fifteen minutes until the desired quantity is administered.

It is not intended to give here a complete résumé of treatment, since there is nothing new, and it is well discussed in the various text-books, as Hare's "System of Practical Therapeutics," Loomis' "Practice," Dercum's "Nervous Diseases," Rotch's "Pediatrics," and others.

Though the patient becomes very sensitive to touch, at times gentle sponging is grateful, and pain is often markedly modified by gently stroking the part with a soft hand. The surface of the body must be kept warm with flannel clothing, and we believe with Bartholow, that cold to the head is not the best treatment. Small blisters to the back of the neck are useful.

The following cases are of special interest for the simultaneous onset, in three of them, and the severity of two, with complete recovery in forty and forty-three days respectively.

The family of H. lived in a dilapidated house of four small rooms during the winter of 1897 and 1898. It consisted of ten members and the house was poorly furnished, there being but three beds and those very scantily equipped. In fact, there was but one bed that was in a condition for occupancy. The food was probably not all that it should have been; in fact, at the onset of the disease, the family became a county charge and it was found necessary to supply linen, while the balance of the family, except just enough to care for the sick, were removed to other quarters. Feb. 23, 1898, three members of the family, the father, aged 54, and two boys, aged 8 and 10, were simultaneously attacked with headache, pain in the back, chill, fever, vomiting and restlessness. The oldest boy suffered least and his proved an abortive case.

After twenty-four hours his symptoms abated and in a week he was practically well, though the petechial eruption, especially on his legs, was far more marked than in the other cases, and the herpetic eruption was not inconsiderable. Both the others became delirious, the delirium being of a noisy character, especially in the man. He was, for a number of days, constantly up and down, often laboring under the delusion that he was ordered either to get up or return to bed, and no assurance to the contrary would induce him to remain in bed. Delusions and hallucinations were a prominent feature of his delirium. Cards, pictures and other wall hangings had to be removed, as they presented to him an army of menacing figures that gave him no slight concern. His speech was not noticeably incoherent, and he would have delusive mental impressions of such lasting effect that he would narrate them as facts, time and again, for days. Delirium did not last so long in the 8 year old boy, though most of the other symptoms were more marked. The herpetic eruption about the mouth was most marked in the man, vesicles forming and rupturing and the lesions coalescing, it presented one large crusted sore. It prevented closure of the mouth and increased the tendency to changes. Petechial spots were noted on the limbs and a light mottling could be seen over the entire body. There was a painful stiffness of the body and limbs, most marked in the right leg, in the knee of which he said he had rheumatism and wanted a plaster put on it. Examination revealed no swelling or redness, and it could be flexed and extended without pain, when the thigh was not flexed at the hip (Kernig's sign). The head was retracted for about two weeks, and for about twice that time he was unable to lower the chin. There was no noticeable opisthotonos. Pain in the back, head and right leg, at first constant, after several weeks became remittent, and lasted throughout the course of the disease. There were photophobia and deafness. The teeth were covered with sordes, and the tongue had a typhoid appearance. About the beginning of the second week there was a sudden discharge of purulent matter, in large quantity, from the nose. It continued for several days. There was general hyperesthesia and movements were generally painful. The pulse ranged from 85 to 110. It was soft and unsteady and stimulants were given, in moderation, after the first or second week. He was a habitual user of intoxicants and in considerable quantity, though he seldom became intoxicated. Temperature ranged from 99 to 102 degrees F., but was at times subnormal. Respiration was not materially modified. During the second week there was albuminuria, which lasted about a week. Potassii acetate was used, with spiritus etheris nitrosi to relieve this complication. During the third week there was vesical paralysis, requiring catheterization. Constipation existed throughout the disease and was relieved with calomel, as indicated. Milk was the main diet, of which he probably took, on an average, a quart a day, and never less than that half that quantity, except during the first few days.

The 8 year old boy had less eruption than either of the others. The herpetic spots were isolated and few in number, although he had some about the mouth, nose, and one on the upper lid of the right eye. His pains were excruciating, except as they were modified by large doses of morphin. There was no region of the body in which pain was not complained of.

Hyperesthesia was marked throughout. Retraction of the head became so marked that deglutition became at times very difficult or impossible. There was extreme opisthotonos, which, with the retraction of the head, continued for fully five weeks. His arms were flexed on the abdomen or chest, the lower limbs drawn up and flexed at the knees. The Kernig symptom was present for some time, but later any attempt at extension became painful. He lay on his side in the manner indicated and, to take nourishment, with some assistance, he would turn on his abdomen, which would throw the retracted head in an upright position so that he could receive it in a fairly natural manner. In assuming this position, however, he never failed to implore his attendant to be careful. There was deafness and intolerance of light. His pulse during the first week ranged from 100 to 120 per minute, but during the second week it dropped to from 55 to 70 (mostly beating about 60) where it remained for some weeks, then it again averaged about 90, and so remained until he was discharged. Temperature for first thirty-six hours was from 100 to 103. After that seldom above 101, and ranged mostly from 99 to 100. At times it was subnormal. Respiration was from 20 to 30, mostly about 24 per minute. During the second, third and fourth weeks it was markedly Cheyne-Stokes in character, the period of apnea lasting as long as twenty-five seconds. The pulse was also much influenced in its rhythm and volume during these changes in the respiration. The Cheyne-Stokes phenomenon was most marked during a period of albuminuria lasting several days, during the fourth week. Twice he had an attack of dyspnea with violent, painful constriction in the chest. His face had the anxious expression of one suffocating, while he tore wildly at the clothes about the chest. The urine was examined in both cases every day or two, both chemically and microscopically. The boy's urine was frequently abundant, with low specific gravity, 1005 alkaline, with excess of triple phosphates. At times, however, it was scanty, with high specific gravity, 1025. The father's urine was generally fairly concentrated.

Both these cases received morphin and the boy took, during his illness, very much more than his father. At times the boy required 0.016 gram every four hours to control the pain. It was, however, given mostly in 0.008 gram doses every two hours, but while giving it this way an extra dose was required at times. The morphin was only given as required, and as he began to improve intervals of half a day to a day would elapse in which it was not necessary to give morphin, but when the pain did recur it would yield to nothing short of the full dose. Even the very last paroxysm of pain required no less than three doses of the morphin. Atropia was always given with the morphin but not increased with it. Small doses of bromid were given throughout the illness. With the large doses of morphin required by the boy, his desire for nourishment did not seem impaired, and it is worthy of note that he took an average of a third more milk than his father, taking seldom less than a quart per day. With a view of promoting gastric digestion dilute hydrochloric acid was given in small doses. It did not, however, improve the digestion, but seemed to aggravate the general symptoms. The potassii acetat, on the other hand, seemed to have a favorable influence. Fowler's solution, in small doses, was tried as a reconstructive after convalescence was established,

but was soon discontinued, as it seemed to increase hyperesthesia and general symptoms of neuritis. We think this remedy, if given at all, should be given cautiously and not so long as symptoms of neuritis are at all marked.

February 25 another boy, aged 15, became sick with symptoms of the disease, but they were mild, and in a week he was again feeling quite well. Two other members of the family, some days later, became sick and were indisposed for several days, but the symptoms did not point sufficiently to the disease to include them. There was, however, one other case in another family, a little girl 8 years old, who was sick fourteen days. Early symptoms were the same as those of cases described. There was, however, in this case, marked dysenteric discharges containing mucus, pus and blood. The case was also markedly intermittent in type. The pain was controlled with acetanilid, no opiate being given. Bromid was given in small quantity.

All these cases were frequently and carefully examined for signs of pulmonary changes, but with negative results, at least so far as physical signs were concerned. The disturbed or slightly increased respiration at times noted was due either to disturbed central innervation or peripheral nerve involvement making normal respiration painful, and hence the more frequent but shallow respirations.

OBSERVATIONS UPON THE SPECIFIC TREATMENT OF TUBERCULOSIS.

Read before the Monroe County (Michigan) Medical Society, April 20, 1898.

BY P. S. ROOT, M.D.

MONROE, MICH.

Briefly, today the pathology of tuberculosis takes into consideration but one real causative factor, the bacillus. Yet apart from this assumption I can not disabuse my mind of the impression that we may and do have a form of phthisis in which this form of bacillus does not directly figure. Such cases are characterized by a low form of inflammatory action, a fibrosis, if you please, with little or no fever. The expectoration is mucopurulent and profuse; consolidation, usually at the base, is present, with the usual classic symptoms. I have made many examinations of the sputum of these cases, finding no bacilli. I take it that this class of cases constitutes the long-drawn-out ones, lasting perhaps for years. They are doubtless susceptible to true tubercular infection, which infection usually runs to a rapid termination. The comparative absence of fever and the failure to find the bacilli, point quite conclusively to this form of consumption. If, then, we have among us this separate type of disease, we perhaps have an explanation of some failures along the lines of specific treatment.

Since the discovery of the bacilli of tuberculosis by Koch, in 1882, there has been a renewed impulse along various lines of investigation, with a view to find some means or remedy inimical to the growth of this bacillus.

If we stop to consider the fearful mortality of consumption we shall see how eminently humane and just are the efforts to mitigate, cure or control this terrible scourge. The true physician will strive to aid in this conquest, will try all things and hold fast to that which is good. In the use of Koch's crude

tuberculin, we found for the first time an agent capable of influencing the tubercular process. That this influence was not salutary, I need not tell you. And yet it was, perhaps, but the too powerful impression of the remedy which increased the degenerative processes. Koch's discovery did not, then, prove to be a distinctly curative agency; but it did serve to demonstrate that in tuberculin we had an agent whose influence upon tuberculosis was specific, and hence has followed the present spirit of investigation by physicians of every country.

In directing attention to a few agents of more or less conceded specific effect, we will confine our remarks to such remedies as have been used hypodermically, because by no other method can we so certainly obtain the real physiologic effect of any medicine. Among the first of these agents we may mention the Shurly-Gibbes treatment, the basis of which was gold and iodine. That these agents were possessed of some virtue I do not doubt; and yet the result has not warranted a very general application. While Drs. Shurly and Gibbes were able to immunize monkeys, the remedies occasioned so much pain in their hypodermic use upon patients that it was difficult to properly carry out the indications. Soon after the treatment was placed before the profession, I obtained some very good results. One patient, whose recovery was thought impossible, is alive and in fair health today. Still, as I said, very few would submit to the pain of these injections. Within the past few months my friend, Dr. E. L. Shurly of Detroit, Mich., has found a solvent for iodine which does not occasion much irritation. The solvent in question is the oil of cloves. It has been found that one and one-half grains of iodine can be dissolved in one drachm of oil of cloves. Of this solution ten minims is given. Better still is it to add an equal amount of sterilized olive oil and then give twenty minims. The injection is given once a day deeply into the thigh or muscles of the back. In the use of this remedy my experience, as well as that of Dr. Shurly, has been fairly good. It is quickly absorbed and little or no irritation follows. While the oil of cloves is used simply as a solvent it may exercise some beneficial effect, for this oil has received considerable commendation in the treatment of tuberculosis, given internally.

The use of nuclein in phthisis is founded upon the theory advanced by Metchnikoff, that the white blood corpuscles act as phagocytes in destroying microorganisms. It has been proven beyond doubt that solutions of nuclein increase leucocytosis to a marked degree. At one time it was thought that this increase was only relative, but experiment shows it to have been absolute. I have been able to observe the increase within two hours after the exhibition of the remedy. If, therefore, the theory of action were to work ideally, we might expect these leucocytes to act as scavengers and to destroy the tubercle bacilli or impair their infective power. To a certain extent these results do follow its use. Professor Vaughan of Ann Arbor has found the remedy of pretty general utility in early manifestations of the disease. The consensus of opinion indicates that nuclein is deserving of further trial and that more or less benefit follows its use. In my own experience, I have noticed temporary improvement in nearly all cases. This improvement, however, has not been sufficiently permanent to inspire me with much confidence. Still, in properly selected cases, good will undoubtedly result

from its use. At present it is placed upon the market in a 5 per cent. solution, which may be given either by the stomach or hypodermically. If given by the mouth it should be upon an empty stomach in from one to two drachm doses three times a day; hypodermically, fifteen to sixty minims, once a day. It must not be inferred that nuclein has any distinctive action upon the tubercle bacilli, but that it acts more or less alike upon all infective germs and should therefore offer some curative aid to their resulting diseases. It is also claimed by Dr. Vaughan to possess direct germicidal action.

Serotherapy.—After the apparent failure of tuberculin, Dr. Maragliano of Genoa devised a serum from the use of which good results are claimed. This serum is supposed to be derived from the horse in a manner somewhat analogous to that of the antitoxin of diphtheria. Dr. Maragliano's method of treatment claims 68 per cent. of improvement. The details of the manufacture and use of this serum are not familiar to the profession of this country, and I have seen no mention of any trial having been made in America. However, Dr. Maragliano's professional reputation is such that his deductions have had no inconsiderable weight with the medical profession of the world.

Dr. P. Paquin of St. Louis, has produced a horse antitubercle serum from the use of which he claims 66 per cent. improvement. Other experimenters have also reported favorably, so that it seems just to accord to these antitoxins a permanent place in the serotherapy of tuberculosis. Both are given hypodermically.

Finally, we come to the consideration of the various modified tuberculins. These are so numerous, and the claims based upon their use so diverse, that I can not hope to give anything like an exhaustive review.

Among the more common may be named antiphthisin, tuberculin R., purified tuberculin, watery extract of tubercle bacilli and oxytuberculin. These various tuberculins differ mainly in the amount of organic matter which they severally contain, also in their composition as to the presence of toxin or antitoxin. The use of some of them is followed by a rise of temperature, somewhat characteristic of the original tuberculin. It is therefore advised to begin with a small dose and increase very gradually. Dr. Karl von Ruck of Asheville, N. C., has used the purified tuberculin in twenty cases with an improvement in 90 per cent. Four cases have made an absolute recovery and five more are rapidly nearing that result. Koch's new tuberculin seems to have failed and the use of antiphthisin has not been followed by very flattering results, due possibly to improper selection of cases. The doses of these preparations are from 0.1 to 3 c.c. No claims are made for advanced cases. Oxytuberculin is a comparatively recent addition to this line and was brought out by Dr. Joseph Hirschfelder of San Francisco, Cal. His first general communication to the profession was made at the meeting of the AMERICAN MEDICAL ASSOCIATION in June of last year. Dr. Hirschfelder is a careful and conservative investigator and his deductions are therefore worthy of some consideration. The method of manufacture consists in gradually adding peroxid of hydrogen to true tuberculin and then sterilizing from 120 to 130 hours. By this "oxidation" process the infective power of the bacilli is destroyed and there is left simply the oxytoxin, the exhibition of which is not followed by interference with the temperature curve. If this toxin be added

to virulent cultures of this germ, growth ceases; and if applied to local tubercular ulcerations, the bacilli disappear and the ulcers heal promptly. Dr. Hirschfelder closes an article in the *Medical News* with these words: "All these tests show conclusively that the oxytuberculin inhibits the growth of the bacillus of tuberculosis. That this is a specific effect and not due to a general antiseptic action, is proved by the facility with which other germs develop in the fluid. From all the statements made I believe I have proved beyond a reasonable doubt that consumption may be cured by the use of oxytuberculin, if the remedy is administered during the early stages of the disease, and that the cure is effected by direct action upon the causative germ."

My own observations in the trial of this remedy are confined to three cases, none of which come under the classification of *early*. Case 1 was one of galloping phthisis, in a patient whose mother and sister had died of tuberculosis. The disease first declared itself in June, 1897. The area of tubercular infiltration spread with almost the rapidity of pneumonitis and very soon involved the lower and part of the upper lobe of the left lung. The sputa contained large numbers of bacilli. Within a short time a large abscess had formed in the central portion of the lung. Temperature ranged from 101 to 104 degrees, pulse from 110 to 120. About this stage of the disease I began the hypodermic use of oxytuberculin in doses of 12 c.c. The results were strikingly beneficial; temperature fell, cough decreased, night sweats were slight and at times none, while the appetite improved and the bacilli could no longer be found. We had, however, to deal with the septic complication incident to the abscess, which without doubt will carry the patient off before long. Were it possible to have drained the abscess cavity, I believe this patient might have recovered, for even at this date the right lung remains unimpaired.

Case 2 was of some three years' standing, or rather is of that length of time, during which time the patient had tubercular pleurisy, two tubercular abscesses of the sternum and a small abscess or cavity in the upper lobe of the left lung. The pulse was rapid, 112, cough annoying, expectoration profuse and well stocked with tubercle bacilli. The temperature ran constantly above 100 degrees. After about six weeks' treatment with oxytuberculin the temperature became normal and has so remained and the bacilli have nearly disappeared from the sputa, with general improvement in nutrition and respiratory power. Dulness has diminished to a marked degree.

Case 3 was one of three years' duration. Both lungs were involved, with a small cavity in the left one. The patient was confined to the bed, with high fever, night sweats and constant cough, bacilli numerous, nutrition poor. Under oxytuberculin she has steadily gained in flesh and the appetite and digestion are good. There is no fever, nor has there been for several weeks. She is constantly about the house and attends to many duties. The last examination of sputum failed to show but few bacilli, and these were difficult to find.

If time had permitted, I would have been pleased to have gone into the details regarding these cases, and yet I think I have shown that this oxytuberculin must be possessed of a wonderful (curative) power. None have been absolutely cured, but each case has demonstrated the benefits derived from this

treatment. Not one of the cases could be classified as early, yet the manifest changes have been such as to point pretty certainly to Dr. Hirschfelder's conclusion that in early cases this remedy will cure a large majority.

The large dose and consequent expense of the oxytuberculin will probably to a certain extent prevent its general use. It costs \$5 for three ounces and is given in doses of from 5 to 20 c.c. hypodermically, daily. Thus far I have used 140 ounces. The injection does not cause reaction or more irritation than an equal amount of water would do. I have never had an abscess or a symptom of one following the injection. If the theory of its action be correct, we have a remedy which will open up a new era in the treatment of tubercular joint diseases; for instead of using iodoform and like antiseptics, we shall simply inject oxytuberculin with possibly absolute results.

In speaking of these agents as specifics it must not be inferred that they offer the means of a certain cure, only so far as the real causative elements are concerned. The pathologic results of the invasion of the tubercular bacilli may remain, and if sufficiently grave, death will result; yet it is to me remarkable that such extensive and rapid repair follows the exhibition of this modified tuberculin. And finally, it seems to me conclusive that, if ever we find a true specific for tuberculosis, it will be among these agents. There are those who maintain that there is no foundation or proof upon which to build our hope for a treatment of tuberculosis by bacterio-therapy. Scientific skepticism is just, if it be predicated upon the correct appreciation of therapeutic deductions. Metaphysically speaking, we do not know the *modus operandi* of these various tuberculins, but for that matter, do we comprehend the intrinsic or dynamic power of any common remedial agent? Shall we say that quinin does not cure malarial fever by its specific action upon the plasmodium malariae? Or that vaccine does not inhibit smallpox? These questions and their details must, therefore, be worked out upon lines of scientific investigation and close observation. If in the end we attain the desired result, what more glorious could redound to the medical profession and to the world? And if we fail, it can not be said of us that we considered the object unworthy our efforts.

TUBERCULOSIS OF THE MAMMARY GLAND.

Read by title at the meeting of the Ohio State Medical Society,
May 6, 1898.

BY ALBERT H. FREIBERG, M.D.

SURGEON TO THE PRESBYTERIAN HOSPITAL; ORTHOPEDIC SURGEON TO THE
CINCINNATI HOSPITAL.
CINCINNATI, OHIO.

Until very recent times tuberculosis of the breast has been considered one of the rarest surgical conditions; this is especially true of primary tuberculosis of this gland. Prior to 1880 we find practically no mention of this condition in surgical treatises save by Astley Cooper and Velpeau. Billroth, in his monograph on diseases of the breast, regarding all previous reports on this subject as inaccurate and lacking histologic confirmation, mentions a case of undoubted tuberculosis of the breast found postmortem in a woman who had died of pulmonary and intestinal tuberculosis. Since this time reports of these cases have multiplied, although the total number of authenticated cases of primary tuberculosis is still considerably below fifty. Of this number less than ten have been contributed

by our own countrymen, two of them having been reported by Powers of Denver. In view of the fact that the diagnosis is by no means always easy, and particularly early in the course of the disease, and regarding the number in which case reports have been added since attention has been drawn to this subject by clinicians, it is fair to presume that the condition of breast tuberculosis is more common than has been heretofore supposed, and that more cases will be brought to light as a growing familiarity with the clinical manifestations makes its recognition possible.

The following case came under my observation, having been under the care of Dr. Irvine of Tolesboro, Kentucky.

Miss Lizzie D., aged 31 years, weight 108 pounds, rather tall and of slight physique, was admitted to my service at the Presbyterian Hospital on Nov. 22, 1897. Both of her parents are living and well. She has four brothers and six sisters living. A brother has pulmonary tuberculosis, and one sister "is in poor health." Two cousins died of consumption. The patient had measles at the age of 20 years. Since then she has had a slight cough with a small amount of frothy expectoration. She has never had hemoptysis. Four years ago she had pneumonia, from which she recovered rather slowly. In January, 1897, she noticed a swelling in the left axilla, which was painful. It was quite large and anticipating suppuration, poultices were applied. Suppuration failed to occur, however, and in time the swelling disappeared. Two weeks after its disappearance she noticed a swelling in the upper and outer quadrant of the left breast. This also was poulticed and disappeared without breaking down. Both of these conditions were quite painful. The pain, without being constant, was sufficiently severe to frequently interfere with sleep. It is described as having been lancinating and radiating from the breast into the axilla and down the arm. It is further described as bearing no relation to the occurrence of menstruation. Gradually swelling and hardening appeared around the left nipple, and during the last two weeks a certain amount of softening seems to have occurred. Temperature 99.2 degrees.

The physical examination shows slightly roughened breathing at the right apex and also some lengthening of the expiratory murmur; lungs otherwise normal; heart normal; considerable enlargement of the left breast; areola enlarged and of a dull cyanotic hue, nipple not retracted. The region of the areola is soft and fluctuation can here be made out. Immediately beneath and surrounding the nipple there is felt a hard mass intimately connected with the glandular tissue but freely movable upon the chest wall. The skin was freely movable over this mass except in the region of the areola where it was in places adherent. Manipulation and pressure was decidedly painful. There was no enlargement of the axillary gland to be felt. Aspiration at the point of fluctuation yielded a small quantity of pale fluid in which tubercle bacilli were demonstrated in small number.

The patient was operated on Nov. 23, 1897; an incision was made into the mass from the nipple toward the axilla and a cavity entered about the size of a hickory-nut, and a quantity of thick cheesy pus evacuated. The entire breast was removed. In view of the entire disappearance of the former enlargement the axilla was not entered. The patient was allowed to return home on November 29, one week after admission, primary union having occurred. On April

6, 1898, Dr. Irvine assured me that the patient had remained entirely well.

By inadvertence the specimen which had been ordered preserved for histologic examination was lost, and I am therefore unable to describe the microscopic appearance. Macroscopically the mass presented a cavity lined with characteristic tubercular granulation tissue and surrounded by an infiltration rather firm in character and extending from the principal mass chiefly toward the axilla. This, together with the discovery of tubercle bacilli, leaves no doubt in my mind as to its tuberculous nature.

Studied from an etiologic point of view it seems rather remarkable that the breast should so seldom be found the seat of tubercular disease. Its anatomic relations and its structure and physiology are such that a frequent tuberculous infection would seem *a priori* probable. But were we even disposed to grant that it escapes clinical recognition fairly often, it must still be regarded as an infrequent occurrence. Powers states that of 185 cases operated on for breast neoplasms, conditions other than mastitis, but one case of tuberculosis was found, and they were all examined microscopically.

The determination of the infection in this particular locality has been explained in three ways: 1. A direct infection through the milk ducts; 2, an infection through the medium of the blood current; 3, by means of the lymph vessels. To these should be added infection by direct extension from a focus situated primarily in one of the contiguous structures. It is true that in this case we should not be dealing with a primary breast tuberculosis, but as Recnick has shown, the primary focus may be very insignificant clinically or even altogether undiscoverable. Direct infection from without, such as might take place through a fissured nipple or through the milk ducts, and infection by means of the blood current can very rarely be proved, but that pregnancy and lactation do exert an influence in this regard is shown by cases reported by Habermaas, Orthmann, Davis and Hanks. The theory of infection through lymphatic channels is given strength, as remarked by Delbet, by the fairly frequent initiatory swelling of the axillary glands. He speaks of no less than seven cases where the affection of the axillary glands was the original clinical manifestation. This requires, however, the assumption of retrograde lymphatic metastasis; a condition which must be looked upon with a degree of incredulity. It would seem more likely that in such cases we had to deal with a primary focus in the breast of inconsiderable extent, and overshadowed clinically by the secondary glandular infection. In the next place it should be remembered that in all probability the glandular enlargement is often indicative of simple inflammatory change and not tuberculous involvement. I have assumed this to be true of my own case.

Pathologically the disease has been described as occurring in two forms, the disseminated and the confluent, the latter of which is by far the more common. In this form we have to deal with one or less often several fairly large nodules, varying in their consistence and appearance upon section according to the amount of caseation and liquefaction which has occurred. Microscopically we find the formation of more or less typical tubercles with their epithelioid and giant cells and accompanying round cell infiltration. Characteristic also are the degenerative changes, but especially, of course, the existence in the tissues

of the tubercle bacilli. Sooner or later there appear marked caseation and liquefaction, and finally secondary infection with pyogenic organisms; there results then the formation of abscesses and sinuses just as in tuberculous processes elsewhere.

Clinically, primary tuberculosis of the breast presents itself in a variety of ways. It is probable from a study of the clinical histories that not infrequently the condition escapes recognition for a long time, not only by the physician but by the patient. This is likely to occur when it progresses slowly in an individual otherwise healthy and when pain is either absent or insignificant. Thus Shattock reports the case of a girl 21 years of age who six years before noticed a lump the size of a hazelnut in the left breast, which was occasionally the seat of slight and transient pain. During the last year the axillary glands were enlarged. Upon removal and histologic examination it proved to be typically tuberculous. On the other hand, the condition may be painful in its very incipency. Not infrequently there is no pain whatever complained of until, with the advent of secondary infection, an acute inflammatory condition develops. As before remarked, the axillary lymphatic enlargement is apparently the first symptom in a considerable proportion of cases. In other cases this lymphatic enlargement has been absent altogether during the whole course. However, it occurs at one time or another in 75 per cent. of all cases, and according to Delbet, suppuration occurs in the lymphatics as a rule before it does in the breast itself. The physical examination of the mamma will, as a rule, disclose a tumor, rather ill-defined, closely connected with the gland substance, but freely movable upon the wall of the chest and beneath the skin. The edge of the mass has not the sharply defined boundary of simple chronic suppurative mastitis and not infrequently processes extend from the principal mass, similar to those of carcinoma. The induration is most frequent in the external segment of the gland and occasionally a firm cord of thickened lymphatics may be felt, continuous with those of the axilla. In consistence the mass is rarely uniform, save in the very earliest stages. Usual is the occurrence in some place or places of softened areas or even pronounced fluctuation. In some chronic cases retraction of the nipple has been described.

The disease is one of young adults chiefly; more than one-half of the cases have been described as occurring between the ages of 25 and 35 years and in women, with very few exceptions. The left side is considerably more often affected than the right.

Our chief interest in breast tuberculosis must be centered in the diagnosis. When liquefaction has occurred to a considerable degree, when sinuses have formed or when the condition affects a young woman of pronounced tuberculous habit, the diagnosis may be extremely easy; on the other hand, when found in one more advanced in years, say 35 or over, and especially when but little softening has occurred, carcinoma may be ruled out with the greatest difficulty, or not at all. This may be true of chronic simple suppurative mastitis also or even of the chronic interstitial form. When any degree of softening has occurred, an exploratory aspiration may determine the diagnosis definitely, as in my own case, by the withdrawal of broken down material in which tubercle bacilli may be found.

A perusal of some of the casuistic literature on the

subject has brought me to the conviction that mammary tuberculosis is by no means as infrequent as has been assumed by some. Thus, Albert speaks of having seen fourteen cases in all and four of them within one year. The application of modern methods of diagnosis, and the examination for tubercle bacilli in particular, together with a more accurate knowledge of the clinical manifestations of mammary tuberculosis will, I truly believe, cause some cases formerly classed as simple chronic abscess to be placed under the rubric of tuberculosis. This refers especially to those cases occurring in quite young unmarried women with no cause apparent for the development of abscess. As such an example I might cite a case reported by Marcus and operated by Ransohoff. A girl of 17 years, unmarried, had been suffering for years with severe pains in the breast, for which a physical basis had not been found. Rather suddenly there developed the symptoms of suppuration. Pus was discharged upon incision, but a fistula remained, necessitating a second operation, at which the gland was found riddled with suppurating foci. In conversation with the operator he acknowledged the possibility of its having been tuberculosis. The patient is known to be enjoying perfect health at present.

The prognosis of this affection is about what we might assume from *a priori* considerations. If treated by radical surgical intervention, a recurrence *in loco* is in the extreme improbable, but the disease, betokening by its very presence a lowered power of resistance to the invasion of tubercle bacilli, and possibly an environment favorable to their development, is apt afterward to appear in other and more vital organs, the lungs in particular, and thus bring about a fatal termination. This has been the later history in quite a number of instances.

In the treatment of mammary tuberculosis we have but to follow well recognized surgical principles. With Robinson and others I believe it unnecessary to enter the axilla unless there be an appreciable enlargement of the lymph glands. In refraining from partial operations upon the breast itself and making the amputation in every recognized case of primary mammary tuberculosis, we can err only on the side of wisdom.

NEPHRECTOMY.

Read before the Michigan State Medical Society, May 6, 1898.

BY J. H. CARSTENS, M.D.

Chief of Staff and Gynecologist to Harper Hospital; Professor of Obstetrics and Clinical Gynecology at the Detroit College of Medicine; Ex President American Association of Obstetricians and Gynecologists, etc.

DETROIT, MICH.

Formerly removal of the kidney was a most formidable operation as the mortality was from 85 to 90 per cent. It was only performed in the very last stages, as a *dernier ressort*. Diagnosis also being very difficult, the morbid conditions for which we now operate and remove the kidney, were treated by internal or external medications. But with the advent of aseptic surgery, great improvement has taken place, and the death record following operations has been so much lessened that, today, it is as low as the general run of

operations involving the peritoneum. The technique has been simplified, so that today no abdominal surgeon hesitates to remove the kidney when indicated.

Diagnosis.—The diagnosis of pathologic conditions requiring removal of the kidney is not easy, the symptoms in many cases being very obscure. Pain in the back is among the symptoms considered indicative of kidney troubles, and still how seldom is this the case. I suppose pain in the back has not once in fifty times any connection with renal disease, but if there is a supposition that this is the case, a careful examination of the urine must be made.

Urine analyses, as a rule, are made very superficially and the simple test for albumin or sugar is not sufficient. A most careful microscopic examination must be made, as well as chemic analysis. The microscope will show us epithelium from various parts of the urinary track, if it is diseased, and by the character of the epithelium we can tell where the disease is. Very often we will find no epithelium, and the urine must be examined repeatedly; and even then in a great many cases of diseases of the kidney of various kinds absolutely nothing will be found in the urine to help in diagnosis. One reason of this is that in a great many of these cases the ureter of the affected kidney is closed up, and consequently we only get the urine from the healthy kidney.

When there is an enlargement, a tumor, it is easy to make a diagnosis, because we get the swelling in the region of the kidney. Still, frequently, adhesions to the liver have taken place and it is absolutely impossible to diagnosticate from disease of the liver; but by careful palpation and percussion, enlargement of the kidney can, as a rule, be readily made out, except in very fat subjects.

Renal calculi, on account of the excruciating pain and the previous history, can more readily be diagnosed. It is only by the most careful attention to the history and progress of the disease, and all the symptoms connected with the particular case, that the diagnosis can be made; but sometimes it is impossible and it can only be made after an exploratory operation. To show how very difficult it is, I mention one case operated on last year.

A woman, 60 years old, was taken with chills and fever, which continued for five months. She was first treated for typhoid fever, then chronic malaria toxemia, having a temperature varying from 102 to 104 degrees. She was finally attended by an able practitioner, who made the diagnosis of septicemia, but could not locate the pus. He sent her to me. The urinary analysis was negative, the abdomen was enlarged, the muscles were rigid so that palpation was impossible; the whole abdomen seemed evenly distended, and the liver seemed enlarged. The woman walked around feeling perfectly well, and had absolutely no pain anywhere, but every few days she would have a severe chill, and had a constant temperature of from 101 to 105 degrees. I put her under an anesthetic and when the abdominal walls were completely relaxed, I could distinctly feel an enlargement below the liver, evidently a kidney filled with pus, with the ureter closed. The next day I removed the kidney, which contained a quart of pus and she made an ideal recovery.

INDICATIONS FOR REMOVAL OF THE KIDNEY.

1. The reflex and other symptoms produced by a movable kidney, sometimes require its removal, after repeated efforts have been made to stitch it in place.

2. Renal calculi, although frequently these can be removed, and the kidney left in place. 2. Incurable urinary fistulae. 4. Suppurating kidneys, hydronephrosis. 5. Tumors of the kidneys, benign or malign.

Technique of the operation.—The kidney may be reached from the loin or from the front through the abdomen. It seems to me that the selection must depend upon the character of the case. If the kidney is small, it can be reached from behind, and removed without opening the abdomen; but if the kidney is large, that is suppurating, hydronephrotic or contains a tumor, it is best to make the opening anteriorly, at the edge of the peritoneum, which must not necessarily be opened, unless the case is obscure and where it is necessary to explore the other abdominal organs.

Frequently there are gall stones complicating these cases, and then it is a good thing to make the incision at the outer edge of the rectus, remove the gall stones, close your peritoneal cavity, and then shove the peritoneum aside, making your way around it to reach the kidney.

In all large growths, it is very difficult to remove the kidney from the rear, difficult to get at blood vessels, and it is advisable to make your incision well forward, say from the anterior superior spine of the ilium straight upward: sometimes make a transverse incision from this, cut toward the back as far as necessary, make a T-shaped incision, although I like to avoid it and usually make a plain straight cut.

All surgeons have found by experience, that cases come in groups, and so I have lately come across a number of cases requiring removal of the kidney.

Case 1.—Mrs. B., aged 58 years, had an immense growth on the left side, which had been coming on for a year. Thirty-three years previously she had fallen and then noticed "a lump on the left side," but it never caused much trouble until a year ago, when it began to enlarge and continued to do so until I saw her. She had passed the menopause and was otherwise in fair health. She did not suffer much from pain, but the increasing size of the tumor alarmed her very much. It was a plain case, of enlarged kidney, probably hydronephrosis. She went to Harper Hospital and I operated on her January 7. I made an incision at the outer edge of the rectus, opened the peritoneum for the purpose of exploring the abdominal cavity, and feeling the right kidney, I found everything all right. I closed the incision in the peritoneum, and made a transverse cut backward for two and one-half inches, shoving the peritoneum to one side. I could easily reach the growth and enucleate. Leaving in a small rubber drain, I closed the incision with silkworm sutures, and the patient made a rapid recovery, being up in ten days.

Case 2.—Miss R., aged 28 years, had been ailing for a year with gradual decline, and swelling in the left side in the region of the kidney. She was sent to me by Dr. Croman of Mt. Clemens. I diagnosticated a suppurating tubercular kidney. She was sent to St. Mary's Hospital. Finding her greatly emaciated, and evidently suffering from tuberculosis, I did not think it advisable to remove the kidney, but simply made a transverse incision between the ribs and the crest of the ilium down to the kidney, which I opened. About a pint of pus was removed, the cavity washed out, and a gauze drain inserted; the latter was removed in forty-eight hours and another one inserted. The patient made a rapid recovery, and in a few days developed a voracious appetite. In two weeks I allowed her to go home, although there was still a discharge, telling her that the kidney would probably have to be removed. She gained for six weeks and then began to decline. She returned to the hospital, where I removed the kidney, February 3, just two months after the first operation, keeping in a good large drain for a few days. Afterward she rapidly gained, and is now perfectly well, there being no evidence of tubercular deposits anywhere else.

Case 3.—Mrs. W., aged 24 years, had always been delicate from childhood, and a swelling had been noticed in the region of the left kidney ever since she could remember. She was married, menstruated regularly, but had no children. During the past three months the growth on the left side increased and caused considerable distress. I considered it a hydronephrotic kidney, and urged its removal. She went to Harper

Hospital, February 22, and I removed it, making a transverse incision just below the ribs. I easily reached the growth after cutting through the muscles. It was certainly cystic but did not seem to be a kidney, so I drew off the fluid and then could easily enucleate it. From its general appearance, although greatly distended, I decided it was a kidney. Examining the cavity again, I was astonished to find another kidney apparently perfectly normal, but small; having put my finger into the peritoneum, I reached over to the right side and found the right kidney normal. The kidney removed had evidently never functionated for years, if ever, one of those rudimentary, supplementary kidneys very rarely found. The woman made an uninterrupted recovery. Dr. Bird, who kindly sent her, reports today that she is feeling better than in years.

Case 4.—Mrs. S., aged 57 years, brought to me from Indiana, had a large tumor filling the abdomen and reaching down to the pelvis. The doctor supposed it to be an enlarged spleen and after careful examination I concurred in this. It reached down to the right iliac fossa, was semi-fluctuating and might have been taken for an ovarian tumor, but careful examination showed that it was connected with the pelvic organs, and the history, which is perfectly clear, showed that it started on the left side just below the ribs and had grown downward, increasing steadily. She went to Harper Hospital and I operated on her, March 9, making an incision from the ribs downward at the outer edge of the left rectus into the peritoneum. Introducing my hand into the abdominal cavity, I found the growth behind the peritoneum. The right kidney was all right. The liver and spleen and all the abdominal organs were normal. The tumor was behind the peritoneum, and evidently connected with the kidney. I closed the incision in the peritoneum and made a cut backward shoving the peritoneum forward. I had little trouble in reaching the growth, tapped it and removed over a gallon of fluid, and could easily shell it out, finding it to be a kidney containing a stone. I put in a gauze drain and sewed up the wound with silkworm sutures. The whole operation took twenty-three minutes. She made a splendid recovery and in fifteen days returned home.

These cases occurring within three months and all recovering, is very fortunate. In all the cases, I use dry sterilized catgut ligatures, chloroform as an anesthetic and, for external sutures, silkworm gut.

DERMOID CYST OF THE OVARY, WITH REPORT OF TWO CASES.

Read before the Union Medical Association of N. E. Ohio, at Akron,
Ohio, Feb. 8, 1898.

BY J. F. FOX, M.D.
NEW PHILADELPHIA, OHIO.

A dermoid cyst may be defined as a heterotopic tumor, containing the products of epithelial proliferation, fat, hair, teeth, cholesterin, bone, etc. They were first described by Lebert in 1852, who applied the term "dermoid" to all cysts lined by a cyst wall resembling in structure that of the external skin. These cysts are found in nearly all parts of the body, the ovaries, testicle, orbit, floor of the mouth, brain, eye, lungs, anterior mediastinum and mesentery. They occur, however, far more frequently in the ovary. In 188 cases of dermoid cysts collected by Lebert, the ovary was found to be the seat of the tumor in 129 cases, being nearly 70 per cent. of the entire number recorded.

According to Senn the wall of a dermoid cyst is composed of connective tissue, its inner surface is often smooth resembling a serous surface, but microscopic examination always reveals an epithelial lining composed, according to the character of the epithelial cells, of one or more layers. If the cysts are lined with columnar or ciliated epithelium, the cells are arranged, as a rule, in a single layer; if on the contrary the matrix represents skin in place of mucous membrane, pavement cells in many layers line the cyst. In cyst wall supplied with the appendages of the skin, these appendages are seen and occupy the

same relation to the cutis as in normal skin. Hair is the most frequent of the cutaneous appendages in dermoids. The hair in a dermoid, called by Virchow lanugo, is fine and of a blonde or light brown color, even in negroes. It is interesting to note that the hair found in ovarian dermoids of aged persons is white, also baldness of the inner surface of dermoids is as often met with as baldness of the scalp; the hair grows, as on the skin, from perfect hair follicles. The teeth found in these cysts are composed of dentine, enamel and cementum, arranged in the same manner as in normal teeth, and they are developed on the same plan.

Senn also claims that the cutaneous lining of dermoid cysts, like the external skin, is subject to the formation of benign and malignant growths. Carcinoma may develop in a dermoid cyst. Benign epithelial tumors, papilloma and adenoma are frequently met with.

In regard to the origin of these peculiar growths, physiologists have been very much at sea; many theories have been advanced; the theory of impaction advanced by Verneuil and accepted by a number of other investigators seems to be the most tenable. At one time the finding one of these growths in the ovary of an unmarried woman was presumptive evidence that she was nuchaste, but this idea was dissipated as soon as examples were reported existing in children. According to the theory of Verneuil, a portion of the blastoderm is forced by pressure into the tissues, there remaining dormant for a while, afterward developing, thus producing by its growth an erratic development of normal tissue.

With reference to the period of life at which they were found, Pigné may be quoted. He analyzed 18 cases with the following results:

Five existed in virgins under 12 years old; 6 in children from six months to 2 years; 4 in the female fetus at term; 3 in fetuses cast off at eight months. On the other hand many cases are reported where they were found at puberty, middle life and old age. Potter reports, in examining postmortem the body of a woman 83 years old, found a similar growth, which though weighing five pounds and nine ounces, had occasioned no symptoms during life. It appears that up to the period of puberty the dermoid occurs oftener than any other form of ovarian tumor.

The contents of these cysts vary considerably in different cases. Sebaceous matter is always found in abundance. Hair is frequently found, short and stubby in some; in others again it is found quite long, as in the oft quoted case of Mundé where a switch of hair was removed measuring five and one-half feet. Again teeth are occasionally found in great numbers. Schnabel found more than one hundred attached to three pieces of bone removed from the walls of a large dermoid cyst in the case of a girl 13 years of age. Another case is reported by Autenrieth in which over three hundred teeth were removed. The presence of teeth constitutes one of the most remarkable features of dermoid cysts. They may be attached to bone or cartilage within the cyst wall, while their crowns extend into its cavity. Sometimes their fangs are surrounded merely by connective tissue; while again the entire tooth may be entirely imbedded in the cyst wall, no portion showing except when exposed by an incision. Occasionally teeth are well formed and of a distinct type. They are usually, however, faulty in point of development and shape, the crown, fang,

enamel or cortical substance may be absent. Caries is claimed to have been found by some writers and denied by others, describing it simply as a phenomenon of wear and absorption. Meckel has shown by his investigations, which have been corroborated by the experience of others, that the teeth of dermoid cysts develop by successive crops, and in many other respects correspond to the normal dental structures. Thus, a preparation in Rokitsky's collection shows the crown of an atrophied tooth resting upon an underlying growing specimen, in a manner which forcibly recalls the natural eruption of the deciduous and permanent teeth. Salter claims, it has also been demonstrated that the teeth are supplied with nerves.

Baumgarten reports a remarkable case where the cyst, besides skin, hair and teeth, contained a body which contained an eye, with a species of convex cornea and epithelium like that of the retina. Nervous tissue, both gray and white, and resembling brain substances as well as nerve-fibers and plain muscular fibers have been repeatedly found in these cysts.

Both ovaries may be simultaneously affected. Out of 15 cases of dermoid cysts operated on by Mundé, in three cases both ovaries were similarly affected. In 31 cases of this disease observed by Doran, 7 were bilateral, while Olshausen found both ovaries affected in 4 out of 16 operations undertaken for removal of these growths. Ponpinel collected 44 cases in which both ovaries were affected. Olshausen collected 2275 cases of ovariectomies, and out of this number there were only 80 cases of dermoid cysts, making 3.5 per cent.

Bradford of Kentucky reports a successful removal of one of these tumors from a girl six and one-half years old. Also, Raemer of Berlin operated successfully on a child twenty months old, removing an ovarian dermoid as large as the patient's head. Collingworth reports the history of a woman in whom both ovaries were apparently involved by dermoids, who had given birth to twelve children and had had three miscarriages, the last three months before the removal of the growths.

The diagnosis of ovarian dermoids, prior to an incision on the operating table, is extremely difficult and in many cases absolutely impossible. The main distinguishing features are, their slow growth when small, greater mobility, sensation of resistance and absence of fluctuation. It should be remembered that true dermoids are invariably unilocular, however it very often happens there is associated with it an ordinary ovarian cyst, in which instance the diagnosis is made more difficult. Inflammation of the interior of the cyst, by the entrance into it of pyogenic microbes occasionally takes place, whereupon the products of the suppurative inflammation of the cyst wall, added to the contents of the cyst causes a rapid enlargement of the tumor. Pelvic abscesses have been noticed and their true dermoid character proven by the removal of long hair through the sinus of the supposed abscess in the posterior vaginal vault. In one case reported by Janvrin of New York, the patient's attention was first attracted by a bunch of hair protruding from the rectum. This, after repeated efforts, she pulled away. Some years later her abdomen began to enlarge, two ovarian tumors were diagnosed and both found to be dermoids on removal, one of which had perforated into the rectum.

Case 1.—Miss L. H., aged 31 years, well nourished, menstruation first appeared at the age of 15, irregular at first, frequently not appearing for four to six months at a time, last few years

regular, complained of tumor noticed in abdomen for over a year, enlarging very slowly, which could now be distinctly detected above the brim of the pelvis. She had attacks of severe pain in the abdomen that would confine her to bed for several days at a time and necessitate a free administration of anodynes for relief. Menstruation was comparatively easy and natural. Examination revealed a tumor somewhat larger than a child's head at birth, springing from the left ovarian region with semi solid contents. Diagnosis as to nature of tumor was in doubt, owing to its slow growth, great amount of pain caused and the partial solid feel of contents; advised operation. A few weeks later, Feb. 14, 1895, operation was made and on opening the abdomen the peritoneum was found considerably congested, also the wall of the tumor thick and very vascular. The contents was so thick it would not flow through large size ovariectomy trocar. On partially withdrawing the trocar a small hair was seen protruding from the wound made in the tumor and a diagnosis of dermoid cyst became easy. The abdominal cavity was now protected with sterilized towels and sponges, and the opening in the sac enlarged and about two quarts of a fatty substance removed, filled with short stubby hair, some muscular tissue and a bone resembling a miniature inferior maxilla, also a switch of hair about the thickness of a baby's wrist and two and one-half feet in length. Accidentally some of the contents of the tumor escaped into the abdominal cavity. The pedicle was ligated, tumor removed and the abdominal cavity irrigated with sterilized salt solution, and the patient made a good recovery.

Case 2.—Miss M. K., aged 28 years, weighing 235 pounds, was examined April 24, 1896. She was suffering considerable pain in the abdomen, loss of appetite, chills and fever, temperature irregular 101 to 102.5 degrees. The abdomen was enormously distended by a fluctuating tumor which was enlarging very rapidly. The uterus was normal in size but driven low down in the pelvis. The tumor mass could be easily felt through the vagina. A diagnosis was made of suppurating ovarian cyst. The general condition of the patient was bad, being confined to bed most of her time for five weeks, which in connection with her fleshiness made operative procedure extremely hazardous.

Operation was made May 14. A great many adhesions were encountered; many of them needed ligating before they could be divided. Over two gallons of gray matter, freely mixed with short hair and small balls of fat were removed with the trocar, the entire mass weighing twenty-two pounds. In closing the wound the peritoneum was sewed with catgut, the muscles with silver wire, the fat, fully four inches in thickness, by four tiers of continuous catgut, the skin also brought together with catgut subcutaneously.

The temperature at once dropped to normal and remained so until the sixth day, when there was a slight show of fever, which continued on the seventh, when we changed the dressings and the wound had united completely without any granulating points. On the eighth and ninth days there was still a temperature slowly increasing. Each day the dressings were changed and search made for a burrowing abscess in the wound. Nothing could be discovered to explain this rise of temperature. On the tenth day the temperature was 102 degrees, and on examining by vagina a small tender mass in Douglas's cul-de-sac was found. The patient was at once placed under the anesthetic, the cul-de-sac freely opened, three or four small dark clots removed, also a small amount of pus and freely irrigated with sterilized water and the cavity lightly packed with iodoform gauze. The temperature again dropped to normal and the patient made a good recovery with no further trouble, and today weighs more than she ever did.

In conclusion, it may be stated that the former teaching, that the escape of a part of the contents of a dermoid cyst into the abdominal cavity at the time of operation, would necessarily be followed by a fatal peritonitis, is probably not correct; a number of cases have been recorded where the accident occurred and patients made a prompt recovery. In the second case the presence of the tumor was not detected until supuration set in, and it commenced to enlarge rapidly.

An Improved Decolorizing Fluid for Nissl's Method is made by mixing 40 c.c. oil of cajuput, 50 c.c. xylol, 50 c.c. creosote and 160 c.c. absolute alcohol. It penetrates the section readily, dissolves the celloidin, which always hinders precise differentiation on account of its avidity for the anilin stains, and absorbs the stain wherever it is not to remain.—De Gothard, *Semaine Méd.*, May 18.

A NEW COMBINATION CHART FOR THE EXAMINATION OF SCHOOL CHILDREN'S EYES AND EARS BY TEACHERS.

Read before the Western Ophthalmological, Otological, Laryngological and Rhinological Association, in Chicago, April 7, 1898.

BY FRANK ALLPORT, M.D.

PROFESSOR OF OPHTHALMOLOGY IN THE CHICAGO POLICLINIC, ETC.
CHICAGO, ILL.

As an adjunct to my method for the systematic examination of school children's eyes by teachers, I have prepared a special compound test card, which I submit. It is based upon the standard types of Snellen, and is called "A Visual and Aural Chart for Schools." Roman numerals are on one side of each line and Arabic on the other. As, notwithstanding frequent instruction and printed directions, I am frequently asked by teachers, "which is the proper line to test by at twenty feet?" I have had printed under the twenty-foot line the following words: "This line should be seen by a normal eye at 20 (xx) feet," which would seem to make the matter perfectly plain.

Under the last line on the card proper, is a half broken line, at which point the lower portion of the compound card should be severed from the upper portion. Just under this line are printed the words, "Please detach by breaking on this line." The card which is thus detached contains the teachers' instructions how to proceed with the tests. The upper or long card, containing Snellen's types is the testing card and should be hung on the wall when in use.

Upon the lower card of instructions is printed the following matter, most of which is already familiar to those who have used this method. Some additions have, however, been made, as for instance the instruction not to expose the card except when in use, the advice not to examine first grade children, the question as to the existence of strabismus, the questions for the development of ear diseases, with their frequent nose and throat obstructions, etc.

INSTRUCTIONS FOR THE EXAMINATION OF SCHOOL CHILDREN'S EYES AND EARS. FOR USE OF PRINCIPALS, TEACHERS, ETC.

Do not expose the card except when in use, as familiarity with its face leads children to learn the letters "by heart."

First grade children need not be examined.

The examination should be made privately and singly, in a room apart from the general school session.

Ascertain if the pupil habitually suffers from inflamed lids or eyes.

Children wearing glasses should be tested with such glasses properly adjusted on the face.

Place a card of Snellen's Test Types on the wall in a good light; do not allow the face of the card to be covered with glass.

The line marked 20 (xx) should be seen at twenty feet, therefore place the pupil twenty feet from the card.

Each eye should be examined separately.

Hold a card over one eye while the other is being examined. Do not press upon the covered eye, as the pressure might induce an incorrect examination.

Have the pupil begin at the top of the test card and read aloud down as far as he can, first with one eye and then with the other.

If the pupil does not habitually suffer from inflamed lids or eyes, and can read a majority of the xx (20) test type with each eye, and does not, upon inquiry, complain of habitually tired and painful eyes and headache after study, his eyes may be considered satisfactory. But if he habitually suffers from

inflamed lids or eyes, or can not read a majority of the xx (20) test type with both eyes, or habitually complains of tired and painful eyes or headache after study, a card of information should be sent to the parent or guardian.

FACTS TO BE ASCERTAINED.

EYES.

1. Does the pupil habitually suffer from inflamed lids or eyes?
2. Does the pupil fail to read a majority of the letters in the number xx (20) line of the Snellen's Test Types, with either eye?
3. Do the eyes and head habitually grow weary and painful after study?
4. Is the pupil probably "cross-eyed?"

EARS

5. Does the pupil complain of carache in either ear?
6. Does matter (pus) or a foul odor proceed from either ear?
7. Does the pupil fail to hear an ordinary voice at twenty feet in a quiet room?

printed (which of course facilitates the work), the names, addresses and office hours of the various free dispensaries may be printed upon the backs of the cards, if it is so desired. If this is done the names of all the reputable Dispensaries in the city should of course be included. Teachers should not exert their influence in favor of any particular Eye or Ear Surgeon or Dispensary.

It will be observed that these cards are non-obligatory in their nature. They do not require anything of the parent, who is at perfect liberty to take notice of the warning card or not, as he sees fit. They simply warn the parent that a probable Eye or Ear disease exists, thus placing the responsibility upon the parent.

Principals and teachers are urged to impress upon pupils and parents the necessity for consulting reputable Eye and Ear Surgeons and not unprofessional tradespeople.

It will be noticed that the language is plain and the instructions simple, in order that they may be easily comprehended by teachers and the laity into whose hands the cards will naturally fall.

The "facts to be ascertained" have been so worded that an affirmative answer to any one of them will indicate that the pupil needs a warning card to take to the parent.

I have several purposes in view in producing this chart. My original method for conducting these tests was to have an oculist appointed by the board of education, who should superintend the tests, collect data, make reports, etc. The examinations were to be made by principals and teachers, and pupils found defective should have their names, conditions, etc., enrolled upon what is called the "statistical blanks," upon which, after due time, is to be written the results of treatment upon the eyes, health and general conduct of the pupil. These blanks are handed to the superintendent and board oculist, who keep them on file and reports on their findings to the board of education.

This is the plan I have advocated and still advocate, but boards of education are not always amenable to argument, and their objections take many forms. Some will not hear to the plan at all; some are willing to have an oculist instruct the principals as to the workings of the plan, but wish him to have no further connection with the schools; some adopt the plan, but will not ask the principals to perform the extra labor of making out the "statistical blanks," and some will not allow the names of the dispensaries printed on the backs of the warning cards, etc. The combination card which I now propose harmonizes with most of the objections, and I think can be adopted under most circumstances.

Many teachers are interested in this work, and are constantly inquiring how they may do it in places where the board has taken no official action along these lines. They can purchase one of these combination cards containing both the test types and instructions, and proceed with the work in their room or school. To this there can certainly be no objection, as the tests are absolutely harmless in every particular.

In case a board does not wish to burden its principals with statistical reports, but wishes the work done in other particulars, these cards may be purchased by the board, which will cover the entire expense, excepting the warning cards.

In the tests in the Chicago schools, which the Chicago Board of Education has requested me to super-

8. Does the pupil fail to hear the tick of a good sized watch at three feet with either ear in a quiet room?

9. Does the pupil fail to breathe properly through either nostril?

10. Is the pupil an habitual "mouth breather?"

If an affirmative answer is found to any of these propositions, the pupil should be given a card or letter of warning to be handed to the parent, which should read something like this:

Dear Sir:

After due consideration, it is believed that your child has some Eye—Ear disease, for which an Eye—Ear* Doctor of recognized standing should be consulted. If you feel unable to consult one at his office, a dispensary will do the work free of charge.

It is earnestly requested that this matter be not neglected, as children with Eye—Ear* diseases can not attain the best results in school.

Respectfully,

Principal School

*Either the word "Eye" or "Ear" may here be crossed out, as may be appropriate for the case. If the pupil has presumably both and an Eye and Ear disease, both words may be left, and the space between the words "Eye" and "Ear" should be filled in with the word "and."

If school authorities desire to have these cards of warning

7. In many cases very early return of motion, after transplantation, may be due to vicarious movements of other muscles than those formerly paralyzed, and not to a regeneration of the latter's nerve supply.

NERVE IMPLANTATION.

Dr. G. CARL HUBER of Ann Arbor, Mich.—I am proud to be able to make some remarks on this interesting case which has been so well presented by the essayist, Dr. Peterson. I became aware of this case after I had completed some experimental work on the repair of nerves after loss of nerve substance, and welcomed, therefore, the opportunity to test some of the conclusions reached, in a clinical case. The question of the repair of an injured nerve is one that has been frequently discussed, both by the experimenter and the surgeon. Opinions differ, however, even yet, as to the manner in which such repair takes place. It may not be amiss, therefore, to review briefly some of my work touching on this question, which has been done in the past ten years. As Dr. Peterson has stated, the views of the histologic process of nerve regeneration may be divided into two groups. One set of investigators, among whom may be mentioned Bünchner, Galeotti and Levi, Kennedy, Ziegler and Wieting, contend for a regeneration of the peripheral segment of a divided nerve from the proliferated nuclei of the old, the degenerated nerve fibers. These cells are looked upon as cells having the value of neuroblasts; embryonic nerve cells. Another set of investigators, among whom may be classed Howell and Huber, Stroebe, Notthafft and Kolster, states that the regeneration of the peripheral end of a divided nerve is through new axis cylinders, which bud from the central, the undegenerated axis cylinders, and grow into the degenerated portion of the nerve. The proliferated nuclei of the sheath of Schwann are, according to this view, not looked upon as neuroblasts, but as cells, probably of neuroblastic origin, which furnish, wholly or in part, the accessory sheaths to the new axis cylinders. The discontinuous origin of the axis cylinder in a regenerating nerve was strongly defended by Bünchner, whose apparently careful work and numerous excellent illustrations did much to bring before investigators the interpretation of the question under consideration. Bünchner's observations may be summarized as follows: He points out that simultaneously with the breaking down of the medullary sheath in a degenerating nerve, there is observed a proliferation, by mitotic cell division, of the nuclei of the sheath of Schwann, and an increase of the protoplasm around these nuclei. The proliferated nuclei become arranged in rows, and the protoplasm begins to show a longitudinal striation. In this striation the author recognizes the first appearance of the fibrillae of the new axis cylinders. These striated bands of protoplasm, formed in the old sheaths, become separated from the remaining protoplasm of the old fibers to form the new nerve fibers. This development of new fibers begins near the wound. They are less fully developed as one proceeds from the injury to the periphery. According to Bünchner, the function of forming these new nerve fibers belongs to the proliferated nuclei of the sheath of Schwann, which he designates as neuroblasts, and regards as nerve cells. The work of Galeotti and Levi may here receive brief mention, as their observations pertain to results obtained on lizards in which the tails were resected and the regeneration of the nerves and motor end organs observed. They found that at the end of the cut nerves, spindle shaped cells are to be observed, which they traced to the proliferating cells of the sheath of Schwann. These cells are rich in protoplasm. They become arranged in rows, and the protoplasm fuses to form bands. In the bands, sometimes in the cells before fusing, the beginnings of the new axis cylinders may be recognized. Ziegler's observations pertaining to the regeneration of nerves corroborate in the main those made by Bünchner. He recognizes the importance of the proliferated nuclei of the sheath of Schwann in the regeneration of nerves, and also observed the striated protoplasm in the old sheaths, from which the new axis cylinders were said to be developed. These new axis cylinders are, according to Ziegler, formed near the wound, in the first place, it would seem, not in connection with the old fibers. This connection is said to be established through a nucleated, protoplasmic plug, which appears at the end of the central fibers. Wieting's work appeared from the Pathological Institute at Marburg, where Bünchner's investigations were made. Wieting confirms Bünchner's observations in full, emphasizing the following points: On the third day, he states, it may be observed that in the undegenerated portion of the central portion of the divided nerve, the axis cylinders terminate in a band of protoplasm, found in the degenerated portion of the central segment. At the point of lesion, cells rich in protoplasm wander out from both the cut ends of the nerve, and arrange themselves in rows between the divided nerve fibers. In the peripheral portion of

the divided nerve, bands of protoplasm are formed in the old fibers.

There is now found in the entire degenerated portion of the injured nerve a mass of protoplasm, out of which are differentiated the new nerve fibers. On the fourth day, occasionally on the third day, there may be observed in the protoplasmic contents of the old sheaths, very fine fibrillae, which always appear first in that portion of the protoplasm joined to the old axis cylinders. From these and similar observations Wieting is led to believe that as soon as a stimulus is received from the old axis cylinders, the neuroblasts lose their identity, flow together, and the fibrillae begin to appear in the protoplasm. These fibrillae are not to be looked upon as an outgrowth of the old axis cylinders, but are developed in the protoplasm derived from the proliferated nuclei of the sheath of Schwann, and this, under the stimulus of the old axis cylinders. These fibrillated bands of protoplasm develop into the new axis cylinders, the medullary sheath developing from the remaining protoplasmic contents of the old sheath, which surrounds the fibrillated portion. The new axis cylinders, medullary sheath and sheath of Schwann are, according to this view, formed from the proliferated nuclei and protoplasm of the sheath of Schwann, of the old, the degenerated fibers, as the result of a stimulus which comes from the central, the undegenerated portion of the nerve. Kennedy describes observations made on four surgical cases. He finds that the new nerve fibers originate in the peripheral as well as the central segment. The new fibers originate from cells within the sheath of Schwann. In the development of the young fibers, the central portion of the primitive protoplasmic thread forms an axis cylinder, and the myelin sheath is deposited in the surrounding protoplasmic zone, which latter remains along with the nucleus as the neuroblastic element of the interannular segment. The formation of new fibers in the peripheral segment occurs, although this is not connected with the central end, but maturation of the fibers is not complete while separation of the ends lasts.

Before discussing the results of investigators who contend for a discontinuous origin of the axis cylinder in the peripheral segment of a regenerating injured nerve, the position of such investigators as believe in an outgrowth of the old axis cylinders into the peripheral portion of a divided nerve, may be briefly stated. Stroebe may here be cited as being the first of the more recent investigators in this field to formulate this view clearly. His observations pertain largely to experiments on rabbits, in which the great auricular nerve was injured by compression. Seven days after such compression, in preparations stained after his anilin blue-saffranin method, young axis cylinders were seen in connection with the central and regenerated axis cylinders; these were traced into the connective tissue, which was developing at the point of injury. Such new axis cylinders, were, in various experiments, followed step for step into the peripheral portion of the nerve, where they were found within or between the old fibers. The regeneration of a divided nerve begins, therefore, at the peripheral end of the central, the undegenerated nerve fibers, as small axis-cylinder buds, which grow to the periphery. The protoplasm and nuclei in the degenerated fibers playing only a passive part in regeneration, in so far as they may, to some extent, at least, guide the down-growing fibers. According to Stroebe, the down-growing axis cylinders possess a thin medullary sheath from their first appearance, showing, however, no nodes of Ranvier, and no segments of Schmidt or Lautermann. These appear about the fifth week, by which time, in the rabbit at least, the new nerve fibers are nearly fully developed. The nuclei of the sheath of Schwann of the degenerated fibers form, according to Stroebe, the sheath of Schwann of the new fibers. Notthafft's observations were, in the main, similar to those quoted from Stroebe. He defends the down-growth of the axis cylinder as the most important phenomena in the regeneration of an injured nerve, and gives diagrams to show the rate of this down growth. He does not, however, give so clear a demonstration as does Stroebe, of the budding of the new axis cylinders from the central, undegenerated axis cylinders, and finds the new fibers at first non-medullated. The observations made by Professor Howell and myself, are usually interpreted as showing a down growth of the axis cylinders from the central end, although this was not so clearly demonstrated by us as by Stroebe. Kennedy and Wieting find in these observations support for a discontinuous origin of the new axis cylinders in the peripheral nerve. We described as the first stage in the regeneration of the peripheral fibers, bands or cords of protoplasm containing nuclei, which resembled developing nerve fibers. These fibers, adopting the nomenclature of Neumann, were spoken of as "embryonic fibers." We were not able to make out an axis cylinder nor a medullary sheath in these fibers, but simply "membranous

sheaths filled with a protoplasmic material in which are numerous nuclei occurring at more or less regular intervals." These fibers seemed to show a low degree of irritability, and seemed more readily stimulated by mechanical stimuli than by electrical. Kennedy regards the fibers, described by us as "embryonic fibers," as nerve fibers, because "when the peripheral segment which contained only such fibers was mechanically irritated, a low degree of irritability and conductivity was found." Stroebe does not regard our embryonic fibers as nerve fibers (neither did we), but as completely degenerated nerves. He is of the opinion that in such cases, where a mechanical or electrical stimulus elicited a response in a portion of the peripheral segment, where only embryonic fibers were found, our histologic methods were insufficient to detect the new axis cylinders which may have been present. I am, from observations made in later work, inclined to accept Stroebe's interpretation of our results. From the investigations of His, on the development of nerves, we have learned that the nerve fibers, the embryo, which resemble the embryonic fibers described by us, thus the name, possess an axis cylinder, in fact, are the axis cylinder branches of nerve cells. Then it must be remembered, a point which Kennedy and Wieting seem to have overlooked, that in our physiologic experiments, irritability in a divided and sutured nerve, or in a nerve crushed with a ligature, did not return before the twenty-first day, and then only near the wound. From that time irritability proceeded centrifugally, and was never well marked until such a time as we were able to find axis cylinders at the seat of stimulation. In the experiments of Büngner and Wieting, the striated protoplasm, in which they see the beginning of the new axis cylinders, appeared as early as the fourth and fifth day after injury to the nerve. As far as I am aware, the irritability or conductivity of this striated protoplasm was not tested by Büngner nor Wieting. In Stroebe's experiments the down-growing axis cylinders reached the wound about the seventh day, and only at a later time were they found in the more peripheral portion of the degenerated nerve. My own experiments on the regeneration of nerves after loss of substance, in which segments of a nerve, a bone tube, or a catgut bundle, were implanted, seem to me of importance in this connection. In all these experiments I was forced to the conclusion that there was a down-growth of axis cylinders from the central portion of the divided nerve, and that it depended entirely on the mechanical conditions, as to whether the down-growing axis cylinders reached the peripheral portion of the divided nerve or not. It seems to me that the experiments of bone tube and catgut implantation were of especial importance in throwing light on this question. In these experiments it seemed to me clearly proven that the new axis cylinders came from the central end, in no instance were there found any axis cylinders in the peripheral portion of the nerve, until the down-growing axis cylinders had reached the peripheral segment. In no instance was there observed any migration of the proliferated nuclei of the sheath of Schwann, either from the peripheral or central end of the resected nerve, which might in any way be regarded as the *anlage* for new axis cylinders, or contribute to the formation of bands of protoplasm in which an axis cylinder differentiation might occur.

Experimental work teaches that an attempt at regeneration occurs after every injury to a peripheral nerve, and that regeneration of the peripheral segment follows if the mechanical conditions for a down-growth of axis cylinder buds from the central end are favorable. Wieting asks this question: "How can such delicate fibers as the new axis cylinders grow through connective tissue, and how can they withstand compression when this connective tissue organizes and contracts?" To this we may answer: "The new axis cylinders grow through embryonic connective tissue, as Stroebe and I have shown. They are hindered in their down-growth, and many of them are deflected from their course, and no doubt many of these new fibers may degenerate again if much connective tissue is formed between the ends of the divided nerve, as, for instance, when a divided nerve is not sutured, or when during a nerve suture, the coaptation of the ends is not accurate. It seems to me this is shown after every nerve injury, especially where there is a loss of nerve substance. The nerve bulb found at the central end of a divided nerve signifies an aborted attempt at nerve repair. In these cases the new axis cylinders grow toward the periphery, but are prevented in their further development by the organization of the connective tissue. It is for this reason that it is necessary to suture carefully after nerve injury, to vivify the ends of the nerve stumps in secondary suture and to use some mechanical device which will protect the down-growing axis cylinders, as will absorb slowly, leaving paths of least resistance in the connective tissue between the divided ends of the nerve, along which the down-

growing axis cylinders may pass in their downward growth. The implantation of a nerve segment, in case an ordinary secondary nerve suture could not be made, was suggested in the case presented by Dr. Peterson, because in the experimental work the implantation of a piece of nerve between the resected ends of an injured nerve seemed to offer the most suitable mechanical conditions for the down-growing axis cylinders. The fibers of the implanted nerve degenerate into fibers consisting of the old sheaths of Schwann, containing nucleated bands of protoplasm, through which, or between which, the down-growing axis cylinders may grow protected, sufficiently at least, from the surrounding connective tissue. This, it seems to me, is an operation that is demanded in every case where an ordinary primary or secondary nerve suture can not be made, owing to the separation of the divided ends of the injured nerve. It is an operation justified by experimental observation, and I may here be allowed the expression of the opinion, and this without in the least attempting to throw discredit on clinical observation, that in this and similar cases experimental observations, histologic, physiologic and pathologic, are more likely to a correct understanding of the question than are observations on clinical cases. The clinician can not expose the nerve at his pleasure, make physiologic tests, and then remove the nerve and study it histologically as can the experimenter. Kennedy, in his cases, was able to remove only a small portion of the nerves operated upon by him.

And I venture to say, that in these same cases, a study of the peripheral portion of the injured nerve would not have revealed new nerve fibers. If nerve fibers had been found in the peripheral portion of the nerve, an operation would not have been needed. The case reported by Dr. Peterson is one I feel sure Kennedy would have interpreted as showing a development of new fibers in the peripheral portion of the divided nerves. As you have seen from the figures thrown on the screen, cross sections of the central end of the peripheral portion of the divided median, showed a few very small medullated fibers. This might be interpreted as showing a development of nerve fibers in the peripheral end, as the distance between the central and peripheral portions of the divided median, measuring about 1 cm., was bridged by connective tissue. In longitudinal sections passing through the peripheral portion of the central part of the median, the intercalary connective tissue and a portion of the central end of the peripheral part of the divided median, small nerve fibers with thin medullary sheaths could be traced from the central to the peripheral part of the median, through the intercalary connective tissue, showing, it seems to me, a down-growth of new nerve fibers from the central end. How far down in the median such new nerve fibers extended we can not say, probably only a short distance. It seems unfortunate, the other features having been worked up so thoroughly and scientifically by Dr. Peterson, that the fingers sent him from Canada were not fixed in such a way that methods used in histology for bringing to view axis cylinders or the medullary sheath could not be used. This would have been of great use in this case from the standpoint of the scientist.

In closing, I can only express my thanks to Dr. Peterson for the opportunity to observe this case, and the Academy for giving me privilege to make these remarks. Your interest in the essay and in the remarks which followed, shows your appreciation of the subject under discussion.

Dr. KIERNAN—What are the nerve elements which occur in the extremities of a part, say the toes or fingers, after amputation; and are there new nerve fibers?

Dr. HUBER—A nerve bulb is formed at the end of the cut nerves and there are new nerve fibers in every bulb. These new nerve fibers grow out from the old nerve. The nerve bulb consists practically of new nerve fibers and connective tissue.

Dr. S. BROWN—I would like to know if this process is not a reduplication of the embryonic development of nerve fibers?

Dr. HUBER—Exactly. It seems to me that there is no doubt that the new nerve fibers grow out as they do in the embryo. This applies more particularly to the axis cylinder. The medullary sheath is of a secondary consideration to the surgeon. If he gets axis cylinder regeneration he does not care so much for the medullary sheath. The medullary sheath, I am inclined to think, is developed from the axis cylinder; the connective tissue part of the nerve is the sheath of Schwann, or the neurolemma.

Dr. TALBOT—Is the nerve tissue admittedly epiblastic in its origin?

Dr. HUBER—It is. The neuron is developed from an epiblastic cell; the supporting tissue of the brain and cord, that is, the neuroglia cells are also of epiblastic origin. Everything that belongs to the neuron proper, and neuroglia tissue is epiblastic in origin, and in no way mesoblastic.

Dr. FERGUSON—Is it possible to cut a nerve and prevent the formation of a nerve bulb?

Dr. HUBER—I do not think that thing can be done. You may possibly, by trimming off the end, prevent it to some extent, but I believe every nerve fiber that is cut away will attempt to regenerate. A nerve bulb is an attempt at regeneration; the nerve fibers try to grow out, no matter how or where a nerve is injured.

Dr. TALBOT—In France many years ago, it was customary to remove a sound tooth from one person and transplant the same in place of a decayed tooth removed in another person. Such teeth often healed without bleaching, which shows that the nerve fibers in the implanted tooth at once became united with the nerve fibers in the jaw, as otherwise the tooth would have changed color. I would also mention the observation that when such teeth were touched with a hot iron pain was felt.

Dr. G. CARL HUBER (closing remarks)—The experimental work of Schiff on "The Replantation of Teeth" goes to show that when a replanted or transplanted tooth makes union this is by means of the alveolar periosteum primarily. He also points out that the pulp in a transplanted tooth always undergoes necrosis. It may regenerate later on, but as I remember, this takes place quite slowly.

Dr. TALBOT—Yes.

Dr. JAMES G. KIERNAN—It seems to me, that there are three subjects which should be discussed here. Not merely the neurologic and pathologic question, but also the surgical. Before a neurologist takes up the question it seems to me better that a surgeon describe the actual results in these cases. Nerve surgery has assumed considerable prominence during the last ten years. At this time the results have not quite reached the standard anticipated. That difference could, with all deference to Dr. Huber's explanation, be accounted for by a difference between the regenerative powers of the animal experimented on and the human being. Take, for example, the work that has been done on bone-tubes. Nerve regenerative power is rarely exercised; as a rule, only the connective tissue part reproduces itself and not the nerve tissue proper.

With regard to the point which Dr. Huber made in which I was very much interested, and which to my mind was to a certain extent supported by a few results in connection with amputation neuralgia and amputation hallucinations, I should be inclined to favor rather strongly surgery alone, the line which Dr. Peterson has indicated. At the same time, the question comes right to my mind, whether with this nerve regeneration we do not have a connective tissue proliferation to correspond or even a greater one. Until that question is settled, one of the practical points, from a neuro-surgical standpoint, remains unsettled. The nerve regeneration in replaced cut-off fingers deserves study from this standpoint.

Dr. A. H. FERGUSON—I should like to draw the attention of the members to the fact that this case of Dr. Peterson was not one of nerve surgery alone; other structures were injured which must be taken into consideration. I refer to the return of motion, and with regard to atrophy or trophic changes that were observed in that hand. The vessels were cut in front of the wrist, all except the radial artery; this would account for some of the congestion, for some of the coldness in the hand, and it might also account in part for a number of other changes.

Nerve transplantation being the subject of the evening, I will simply read to you a report of my own case, which occurred five years ago, but which report I am sorry to say is not as complete as it might be, nor as replete with material as that of Dr. Peterson, but I think has a scientific value.

Miss M., age 18 years, presented herself at my office on May 3, 1893, with a tumor situated in the course of the median nerve about an inch and a half above the left wrist joint. It was painful to the touch, and pain was referred to the peripheral distribution of the nerve, especially in the index and middle fingers. Her suffering was gradually increasing in severity, and night pains were experienced. The growth was first noticed in February, 1893. Changes in the weather appeared to bring on pains in the hand. On May 9, 1893, assisted by Dr. Versailles, I removed the tumor under cocaine anesthesia, through a lateral semilunar skin incision. It was found necessary to inject cocaine into the nerve above the tumor before manipulation of it could be tolerated. By blunt dissection an effort was made to separate the nerve-fibers from the growth, but without much success. The tumor was almost round in shape. It measured an inch in its longest diameter, which was parallel to the course of the nerve. The nerve was severed about an eighth of an inch above and below the tumor. The distance between the ends of the nerve was bridged over with four strands of chronic catgut (No. 1, Seabury & Johnson), which brought the ends closer together than an inch. The wound was closed and dressed. A McNaughton splint was

applied, putting the forearm, wrist and palm at rest, the fingers flexing over the end of the splint. The case was not seen by me for a week, when the dressings were removed, wound found healed, the skin sutures removed and the limb dressed as before. There was no return of sensation, and motion was not attempted. At the end of another week all dressings were removed and left off, and gentle friction and passive motion advised. She complained of a soreness in her hand. During the following three or four weeks the hand was weak and numb. A rubber ball was given her to exercise the fingers. Some days the finger and thumb appeared to be stronger than previously, and again they appeared to lose the strength gained. At the end of six weeks there was practically no return of motor or sensory function. The grasp was imperfect, and she could not feel the prick of a pin over the outer half of the palm, the palmar surface of the thumb, index and middle fingers. There was some sensation on the radial side of the ring finger. The tips of the thumb, index and middle fingers could be pricked with a pin without being felt. The tip of the ring finger was sensitive. Sensation was also absent on the dorsal aspect of the thumb, and two adjacent fingers immediately below the nails.

Three months after the operation (Aug. 12, 1893), the ball of the thumb was noticed to have atrophied. The grasp had not improved. The anesthesia on the palmar surface persisted, but she claimed that on being pricked several times in quick succession on the dorsal aspect of the thumb and fingers, to feel that something had been done. Return of sensation in these regions is put down as doubtful. Transplantation of a nerve from an animal was determined and carried out August 12, 1893. About an inch and a third was removed from the left sciatic nerve of a pup and transplanted into her arm in the following manner: Chloroform was administered to both. The old semilunar scar was followed and removed from her arm, a flap raised, the catgut was absorbed, dense scar tissue extended between the ends of the nerve, the proximal end somewhat bulbous, the distal about normal in size, but somewhat fibrous, the ends were vivified by transverse incisions and the nerve from the dog sutured in place with fine silk. I saw her again on the third day. She saluted me with the assertion that she could feel with all her fingers except the middle one, which I verified by pricking them with a pin. I saw her again on the eighth day. She now complained of soreness and hyperesthesia in the distribution of the nerve to the hand. From this time on the sensation of the limb became more and more normal. Motion improved gradually, but was vasculating and painful. Creeping sensations ran down the fingers occasionally. She was then under my observation for a month, at the end of which time she had a good useful hand, having been restored to about two-thirds of its function. I might say that passive motion was commenced about the end of this second week. She used to rub it a great deal with oils of different kinds, in which she was encouraged. Two years afterward (1895), I saw her for a few minutes on the street. She said her hand was still lame, but useful, and did not pain her. She could feel anything larger than a fine needle and thread or horse hair. I noticed that the atrophy persisted, and that the grasp of the hand was not fully restored. When Dr. Kiernan asked me to discuss Dr. Peterson's paper, I at once wrote to this lady, and the following reply was made to a series of questions I wished her to answer, and received yesterday: "I will just answer all your questions by saying that my hand is, may be, a little stronger than when you saw me last in Winnipeg. The feeling is about the same, and my hand near the thumb is still wasted." I do not understand how the sensation returns so rapidly unless the continuity of the median has something to do with it when we transplant a nerve. If it were due to the impressions sent along other tracks those impressions should have existed primarily immediately after the first injury.

Dr. E. S. TALBOT—Transplantation of nerve tissue is not new to the dental surgeon. Even one hundred years ago, the French nobility had their decayed teeth removed and healthy teeth of the peasants substituted. When these teeth were extracted, the nerve tissues as well as blood vessels were severed at the apex, but sensation and vitality were eventually restored.

This is true at the present day. It is not an uncommon thing for physicians and dentists to replace teeth that have been knocked out. It is impossible to say whether they unite or not. I can only say that discoloration of the tooth and alveolar abscess do not occur, which would be the case if union did not take place. By the common practice in such cases of placing a heated instrument upon the tooth, the patient responds to sensation. These teeth remain in a healthy condition in many cases through life.

Dr. W. X. SUDDUTH—This is a subject that has a great deal of interest for me, because I can speak from two standpoints, that of a scientific observer and also as a patient. In the fall of 1878, as some of you know, I was in Wyoming Territory. I had been interested in the cattle business since 1873, and finding that I was unable to secure as good a market as I wanted I established meat markets in the northern part of Colorado, and had my agents at different points attending to the sale of meat that was taken to them. Being called to a mining camp in northern Colorado, and my agent there anxious to take advantage of the occasion to take a vacation (which means to go on a drunk), I had to take charge of the market, and having occasion to cut a rib-roast, I cut it through with a knife and started to use the cleaver, and in doing so held the ribs apart with my left hand, but in using the cleaver the blade went too far and struck me right on the upper portion of the wrist, cutting it to the bone, severing blood vessels, ulnar and median nerves, and as a result, having no means of attending it antiseptically, antiseptics being practically unknown in those days, a cicatrix formed between the cut ends, followed by paralysis of the abductor muscles with loss of sensation and loss of the use of the thumb for any fine manipulations. This lasted for several years, and in the meantime I returned to college work, experimental and embryologic, engaging my attention especially to nerve tissues, and came to the conclusion from experiments made on rabbits that the cicatricial tissue prevented the union of the nerve ends, as Dr. Huber has shown you, and in 1884 I spoke to Dr. Garretson, who was then living in Philadelphia, but since deceased, and he cut down and removed the cicatricial tissue and brought the cut ends of the nerves together by the only process we then knew (buried sutures), the wound healing by first intention. Following the operation sensation did not return at once, possibly by reason of lack of adjustment of the ends, as the operation was according to our knowledge of today, somewhat crude. Still sensation gradually returned and has been steadily improving till the present time. This case has never been published, because I have not discontinued my observations as yet. There is no question but what, in this particular case, sensation improved from the distal ends of the central nerve, that is, from the upper portion; it was not through a collateral division, because if it had in the six years after it occurred before operation it would have been restored. The anastomosis came from the union of the ends of the nerve and gradually the thumb has been restored to its full rotundity and the strength of the muscle improved and now all that remains is a certain tingling sensation when it is touched, and which is gradually getting better and better all the time.

Dr. HUBER—Just the thumb alone lost sensation?

Dr. SUDDUTH—Yes. This whole question is one of vital interest to the embryologist, as to whether this regeneration of nerve tissue is through an inside extension of the neuroblast from the root nerve or whether there is a transmission or transformation of the embryonic connective tissue into nerve tissue. My observations made upon peripheral nerve endings, although not done with the later methods, the Weigert method being the one used at that time, still we got fair results. Perhaps the best work I have done along that line was in the development of peripheral nerves in the pulps of the teeth. Prior to the eruption of the teeth no nerve-fibers are to be observed at all, and the apical foramen of the tooth is fairly well developed, and yet at a certain point, the development of these peripheral nerve-fibers seems to come from the mesoblastic tissue of the pulp itself.

The point raised by Dr. Talbot as to the restoration of sense of feeling in the implanted or transplanted tooth is a good one clinically, but so far as I know no scientific work has been done to demonstrate the regeneration of these fibers. That there is a return of sensation there is no doubt, but that leads up to the subject of redevelopment of excised nerve. I have assisted in and performed operations of excision of the inferior dental nerve for neuralgia of the face, and we took the precaution to insert wooden plugs, also other kinds, into the dental foramen.

Dr. HUBER—You have a bone-tube there?

Dr. SUDDUTH—Yes. And in our cases neuralgia returned, so that we had a very positive demonstration of redevelopment of the nerve-fibers, even where the nerve was excised. In those cases invariably the restoration of the excised portion, is from the trunk end of the nerve, not from the peripheral portion, except a plug was inserted to prevent it, at the upper end of the canal. This question is one fraught with great interest, and one that can not be discussed to any extent in the time that is allotted.

Permit me to express my thanks and appreciation to Doctors Peterson and Huber for their work and contributions to the Academy.

Dr. S. A. MATTHEWS—In regard to the quick return of sens-

ation to the part rendered anesthetic by division of its nerve supply, after the peripheral and proximal ends of the cut nerves are reunited, physiologic experiments suggest the following explanation, which at present can only be considered a suggestion: We have quite good reason to think that sensation is not wholly supplied to a part by one nerve trunk, or from one segment of the cord, but that there is an intermingling of collateral sensory nerve fibers with those normally furnishing sensation to the part through which sensation may be supplied after section of the main nerve supply.

But this does not answer the question raised by Dr. Ferguson, why these collateral nerve fibers do not supply sensation immediately after section of the main nerve trunk, but do not come into play until the nerve trunk is again reunited. This can only be explained by assuming that at the proximal cut end of the nerve there is a continuous irritation. The sensory impulses set up by this irritation pass into the cord, and seem to have an inhibitory influence on the sensory impulses passing to the cord along the collateral fibers, and so long as this irritation continues, so long are the collateral sensory impulses inhibited. This has, to a certain extent, been proven experimentally, *i. e.*, it has been shown that an irritation of a set of sensory nerve-fibers may inhibit the same sensation, coming into the cord through other paths.

Then the explanation comes to this, that when the cut ends of the sectioned nerve are reunited the irritation which has been continuous at the proximal end is removed, thus permitting the collateral sensory nerve supply to the anesthetic part to come into play. I would not have you think this definitely proven, but only offer this as a suggestion based upon certain physiologic experiments.

Also, Dr. Peterson has spoken of certain variations noticed in the function of both sensory and motor nerves. This is in all probability due to changes in the nutrition of the muscle cells which they supply. It has been proven experimentally that living tissue, especially muscle tissue (contractile), if placed under conditions unfavorable to its nutrition, as the accumulation of poisonous products, etc., tends to do away with the nerve influence of the tissue. This has been shown to be true by letting the metabolic products accumulate in active muscle to such an extent that the nerve supply has no longer any influence. Then if a normal salt solution be permitted to circulate through the muscle, washing out the poisonous products, the nerve influence returns. In fact, I have often observed this phenomenon in studying the influence of poisons on contractile tissue, and it is well known that variations in the nutrition of muscle tissue causes variations in the influence of the nerves supplying such tissue.

Dr. SANGER BROWN—The careful and thorough observation and concise expression in the paper we have just listened to reflect much credit upon the author. The Academy is certainly to be congratulated upon the accession of the essayist to its membership. I also have been very glad to hear the summary of our present knowledge regarding the regeneration of nerve elements by so competent an authority as Professor Huber. From all observations and experiments at present available, it would seem quite reasonable to assume the existence of collateral paths for the conduction of both motor and sensory impulses, similar to what is observed in the circulation, and in a similar way, to assume that when the more ordinary paths are interrupted the collateral paths are susceptible of development, and that the number and magnitude of these collateral paths vary greatly in different individuals. Assuming this hypothesis to be true, the explanation of much of the improvement that occurs from a few hours to a few days after the operation in these cases is, to my mind, reasonably explained on the ground of suggestion; that is to say, these collateral paths existing, suggestion would effect the necessary stimulus in the cortex to produce the result observed. Though not quite all the phenomena of rapid improvement may be satisfactorily explained on the hypothesis of suggestion, many of them are satisfactorily so explained. Certainly it is not reasonable to assume that the nervous energy could proceed through, perhaps, several centimeters of the inserted nerve trunk and then through a distal segment of nerve trunk devoid of axial cylinders, whereas all the conditions of the operation and of the influence brought to bear upon the mind of the patient after the operation are usually pre-eminently calculated to produce a powerfully suggestive effect.

Dr. PETERSON—It is only in exceptional cases that we will be able to determine whether the connective tissue has been increased at the point of lesion after our nerve transplantation cases. Therefore, Dr. Kiernan's criticism will not hold, and we will have to depend upon the results of animal experimentation.

It is to be regretted that the amputated fingers were not

preserved in Müller's fluid, as the microscopic examination when the proper method of staining the axis cylinders could have been used, would have been very interesting. The patient's second finger is now troubling him, and if it be amputated I will see that it is preserved in the proper fluid.

It does not seem to me that Dr. Ferguson's criticism, that in the case reported we were not dealing with trophic changes due to section of nerves alone, should have much weight. It is true that the ulnar artery was also severed, but this will not explain the presence of the trophic changes, and if the changes noted were due to a loss of arterial supply, it is difficult to explain why the nutrition of the hand improved so markedly after the operation upon the nerves alone. A study of reported cases will also show that the same conditions as were present in the case reported before and after the operation may exist where the arterial supply has not been interfered with.

As suggested by Dr. Brown, one is naturally suspicious that the mental attitude of the patient may have a bearing upon the early return of sensation. I think this factor can be safely eliminated in the present case, however. It will also fail to explain such rapid return of sensation as was quoted in the paper, when there was actual loss of nerve substance. The reason why sensation is not conveyed through the collateral nerve paths immediately after the injury and is later on after an operation, must be determined by further experimental work.

Cincinnati Academy of Medicine.

Meeting held June 6, 1898.

Dr. HORACE WHITACRE read a paper on

THE USE OF IRRIGATION AND WET APPLICATIONS IN SEPTIC SURGERY.

The paper opened with a brief review of septic conditions calling for these measures, including cellulitis, septic machine wounds, compound fracture, head wounds and pelvic cases, with a division of septic wounds into the local and spreading type of infection. The great lack of conservatism in the treatment of such conditions was deprecated and the irrigation methods offered as a valuable aid in saving tissue. In considering the use of wet applications, a cellulitis of the hand was taken as an example, where a scratch is the point of infection, the finger swollen and painful, back of the hand reddened and puffed, and lines running up the forearm. The pathologic condition of the tissues was fully described and the essential lesion shown to be a growth of the virulent micro organisms within and along the line of the deep lymphatics. From this the indications for treatment are shown to be some antiseptic that will be absorbed by the lymphatics and carried along these channels to destroy the germs. The wound is too small to absorb and the skin is an osmotic membrane covered by fat and skin sebum and saturated with cholesterolin fats, so that only those substances will osmose which will mix with this covering. Such substances are carbolic acid, acetate of lead, acetate of aluminum, etc., while those that will not are $HgCl_2$, $NaCl$, KI , etc. It was shown that a voluminous wet dressing of 1 to 80 carbolic acid retained moisture and heat and an antiseptic kept in contact with the skin for constant transfer to the seat of germ activity; also that $HgCl_2$ could have no such effect. This dressing is of value in all types of spreading inflammation and serves to abort many such attacks. The form of irrigation known as submersion, in warm water or weak antiseptic solution, was next taken up in its application to: 1. Cases of continued cellulitis where repeated incisions had been made, through and through drainage established and painstaking dressings persisted in, yet the tissues remained sodden and infiltrated, joints are destroyed, and the loss of the part is imminent. 2. Severe lacerated injuries, including compound fractures, where septic infection is present, the tissues widely involved and the wound has a pork-like appearance. 3. For the purpose of maintaining life in tissues where the circulation is cut off by lacerating injuries of the larger blood vessels (infection present or not), and by plaster, splint or other bandage. Under 1 and 2 the advantages gained were: 1. Water by direct solution and by diffusion takes up and carries away large quantities of the toxic, crystalloid, chemic products of the bacteria which are the source of the entire local and constitutional reaction. This, based on the fact that it is not the bacteria that are harming the cell or the body in general, but the toxin which by acting on the cell lowers its vitality and gives access to the bacteria, or by diffusion into the blood acts on the thermogenic center to produce fever, or in the heart, liver or kidney to produce cloudy swelling and fatty degeneration. In submersion the diffusion process is into the water instead of the blood. 2. Water alone is healing. 3. Moisture

prevents exsiccation of the secretions, relieves tension and renders the tissues soft. 4. Heat to a surprising degree retains and brings back life to tissues that otherwise would be hopelessly lost. 5. Any antiseptic, such as carbolic acid in very weak solution, would be absorbed into the lymphatics and the tissues saturated by an antiseptic agent in such strength as to inhibit the growth of germs at their seat of development. Clinically the change in the patient is a prompt drop in temperature, diminished edema, the wounds clean up and tissues are saved that had seemed already lost. A special point was made of the natural resisting forces of the body represented by the vital energies of the cell; the fact was recalled that great numbers of bacteria can be eliminated without the slightest damage to the system, and that at other times an infection resisted with very slight artificial resistance. These facts call for agents which will stimulate the nutrition of the cell and not for strong agents which will lower the resisting power forces. Under 3 (submersion) it was shown: 1. That blood remains fluid and the vessel walls normal in the distal portion of an injured or obstructed blood vessel. 2. That the heat of a part is very rapidly diminished when the blood supply is cut off, a condition favoring the rapid death of tissue. The case of a trephine button was cited, also the fact that a Thiersch skin-graft may live twenty-four hours if kept in normal salt solution, and take well when applied. These and many other things would show that cells may live a long time without blood supply, and the use of submersion is based upon the fact that we artificially maintain conditions of heat favorable to the life of the cell until anastomotic circulation can establish itself. Irrigation by a constant stream was next considered and was again stated to be based upon the fact that the great object in septic surgery is to obtain good drainage, and that no permanent dressing, no matter how frequently changed, affords perfect drainage, but leaves secretions in contact with the wound for absorption. The measure consists in conducting a gentle stream of 1 to 1000 carbolic or to 10,000 $HgCl_2$ to the bottom of a septic wound and allowing this to bathe the wound constantly. It was stated that most of the germs were probably beyond the reach of an antiseptic and deeper in the tissues but the advantages seemed: 1. The mechanical removal of secretions and debris. 2. The prevention of the entrance of pathogenic bacteria. 3. The diffusion of toxins externally. 4. In carbolic acid we have an antiseptic that will penetrate albuminous matter and the tissues. 5. The main advantage is good results. The measure fails: 1. Because the flow of fluid is too slow. 2. The fluid often runs back along the tube and reaches none of the important interstices of the wound. 3. Irrigating fluids are often too strong. The application to pelvic cases was considered in its mechanical difficulties and much stress was placed on the proper placing of the irrigating tube of soft rubber at the bottom of Douglas cul-de-sac, and often a second tube by means of a Y attachment into the lateral recesses.

Chicago Ophthalmological and Otological Society.

Regular Meeting, April 12, 1898.

Dr. COLEMAN in the Chair.

Dr. WESCOTT showed a case of

CONGENITAL CATARACT.

The patient, 27 years old, says he is one of many children having the same condition. Two of his relatives had been operated upon, and one had been given better vision. He is unable to tell the nature of the operation. Vision in one eye is 20_{200} , and in the other 20_{100} ; not improved under atropin. The opacity is so large that when the pupil is fully dilated there is only a narrow ring of transparent lens.

Dr. HALE—I have had one case similar to the one shown by Dr. Wescott, and operated on one eye with a resulting vision of 20_{100} . This patient gets along very well by using his unoperated eye for near, but with glasses he complains that he can not see quickly enough on account of the asymmetry.

Dr. TILLEY—The fact that there is no improvement under atropin is considerably against the hope of vision being greatly restored.

Dr. COLEMAN—I would operate on the worst eye of the two if there is any possibility of improving vision. Asymmetry is an objection, but not so great as commonly thought. I have had several patients get good binocular vision with correction. I would not expect to improve this case by an iridectomy, but think discussion the proper thing. Extraction of these lenses has not been a success in my hands.

SUPPURATING LID.

Dr. C. P. PINCKARD—This gentleman has kindly consented

to appear before us this evening to show an interesting condition of the lids, a condition I have not seen anything like before. It started some six weeks ago in the form of a sty which was opened and for a day or two apparently got better. Shortly after, however, the lid began to swell considerably and an ulcerative process commenced in the neighborhood of the sty, involving the conjunctival border of the lid for perhaps half an inch toward the outer canthus. Also one of the Meibomian glands upon the center of the lid began to suppurate. There was no previous chalazion, but from the gland extending clear through the duct to the border of the lid the same process started up. The peculiarity connected with the case is the character of the process. Along the border of the lid it destroyed the tissue very rapidly, so that in wiping it off there was not only considerable pus but shreds of the lid tissue itself. The process in the Meibomian gland broke through into the conjunctiva and a considerable quantity of the tarsus has been destroyed as well as the superficial parts of the conjunctiva extending down to the border of the lid. The first treatment was mild, followed, however, by strong escharotics, such as the use of nitrate of silver and powerful solutions of corrosive sublimate, but all the time the pathologic process kept advancing. About ten days ago, when the case first came into my care, ichthyol was started and seemed to have a beneficial effect on the diseased condition, but not much. After two or three days, the improvement not being marked, I started chinisol solution in the strength of 1 to 1500, and from that time it has continued to improve. The principal point is as to the nature of the process. There is absolutely no history of any general infection. Dr. Evans, in the Columbus Medical Laboratory, examined some of the pus and tissue from the edge of the ulcer for tubercle bacilli with negative results. An inoculation was made in gelatin, and after two days there was no growth. Then an inoculation was made in agar, and then in agar and glycerin, and kept in the incubator for twenty-four hours with no result. So we have nothing whatever to go by in this destructive process of the lid. If it be tuberculosis of the lid it certainly assumes a very unusual form. The hair follicles are not involved. The ulcer is now in the healing stage but shows the large amount of necrosis which has taken place.

Dr. ROBERT TILLEY—The case reported by Dr. Pinckard is interesting as well as curious. Chinisol, of which he speaks, is being lauded as a valuable antiseptic, and yet at the same time there does not seem to be any vestige of any bacteria to be found on the minutest observation. Chinisol, which is manufactured by a Hamburg firm, is difficult to get, but I have used it somewhat with apparent satisfaction under certain circumstances. I suppose the still more recent article, protargol, may have the same effect.

Dr. C. P. PINCKARD—This must be from our present knowledge a septic process, in spite of the fact that no culture could be made, and that powerful antiseptics like silver and corrosive had no beneficial effect. They made it worse, and during their use the disease spread rapidly, the tissue broke down, and there were shreds of tissue at the bottom of the ulcer. The ichthyol, which is not an escharotic, and the chinisol, which has a mild action, seemed to at once act favorably.

EMBOLISM OF ONE OF THE BRANCHES OF THE CENTRAL ARTERY OF THE RETINA.

Dr. H. W. WOODRUFF of Joliet, Ill.—I show you a case in which there occurred sudden diminution of vision in the left eye in a young lady 20 years of age. It came on last Thursday evening while she was at home. She has had blurring of the eyes before, but this condition was something entirely different from anything she had previously experienced. She has a refractive error in both eyes. I saw her yesterday afternoon for the first time, and found on ophthalmic examination what is undoubtedly an embolism of one of the branches of the central artery of the retina. The light edematous area is to be seen toward the temporal side of the disc. The veins are plainly visible over this light area. Her direct vision is $20/120$. There is a large ecotoma in the field of vision corresponding to the occluded area. There is no sign of any kidney or heart disease. Her urine has been examined and shows no albumin and but a trace of sugar.

Dr. ALBERT B. HALE read a paper entitled

STATISTIC REVIEW OF FIVE HUNDRED CONSECUTIVE CASES PRESENTED AT THE HEBREW CHARITIES DISPENSARY.

In this summary it is not meant that there were only so many cases of trachoma or of iritis, etc., but the diagnosis of the most important sign or symptom for which the patient wished treatment was considered; and therefore many examples of trachoma or refractive error are not put down in the table. Cases called amblyopia are those which require further examination, for which they failed to come. Operations not mentioned

in the table were done as required. I can not explain why there have been so few cases of choroidal or retinal degeneration, because I have a large material in myopia with all its associated effects upon the fundus, and European clinics dealing with the same races report more instances of choroiditis and retinitis. I notice, too, that injuries are rare. This I ascribe to the fact that as a class this people is not industrial, but domestic and commercial. Cases of gonorrheal conjunctivitis are rare, probably because of the custom of early marriage and of the commendable virtue of both male and female parents.

I present the table herewith.

	Per cent.	Schwabe's Leipzig percentages from 15,675 cases.
1. Diseases of the lids: Sty 14, chalazia 6, cysts 1, phlegmon 5, fissure 1, pediculi 2, insect bites 2, papillomata 1, burns 1, blepharitis 56; total, 89.	17.8	10.10
2. Diseases of the lachrymal apparatus: Dacryocystitis, 10.	2.0	2.19
3. Diseases of the conjunctiva: Injuries 11, cyst 1, foreign bodies 22, trachoma 24, pterygia 1, herpes 1; inflammations: Simple acute 51, simple chronic 21, follicular 2, phlyctenular 16; total, 150.	30.0	18.12
4. Diseases of the cornea: Injuries 5, foreign bodies 20, tattooing 1; inflammations: Simple infiltrate 9, vascular 3, ulcerous 21; total, 59.	11.8	19.19
5. Diseases of the iris: Inflammations: Plastic 5, serous 1; total, 6.	1.2	1.59
6. Diseases of the choroid: Choroiditis disseminated, 1.	0.2	1.64
7. Glaucoma, 3.	0.6	0.65
8. Cataract: Congenital 1, senile 7; total, 8.	1.6	2.81
9. Injury to bulb, 6.	1.2	0.56
10. Refraction: Myopia 34, hyperopia 63, astigmatism 3, presbyopia 26, squint 12, nystagmus 1; total, 139.	27.8	36.31
11. Diseases of the optic nerve 4.	0.8	2.22
12. Amblyopia and amaurosis 25.	5.0	0.44
	100	

Dr. PINCKARD—At the eye clinic of the Michael Reese Hospital, where we have the same class of people to deal with, we see many cases of choroiditis. I do not recall the exact percentage, but it is comparatively large.

Dr. COLEMAN—I am surprised to learn the large percentage of myopia in Dr. Hale's report. I can safely state that not more than 10 per cent. of my cases are myopes. I have little faith in statistics of refraction unless the cases are all tested under mydiatics.

Dr. WESCOTT—I do not believe I see a case of myopia once in twenty-five cases. It is a rare condition compared with hyperopia with me.

Dr. MANN—I meet with a larger percentage of cases of myopia in the Germans, Russians and Poles than in any other class of people.

Dr. HALE—All the cases reported as myopia were examined under a mydiatic.

Dr. ELMER A. LAWBAUGH reported a case of

BILATERAL TEMPORAL HEMIANOPSIA.

The case I have to report this evening is one of bilateral temporal hemianopsia in acromegaly. Though twelve years have passed since P. Marie first established and described the typical characteristics of this disorder, we know comparatively little more concerning the etiology, pathology and treatment of this disease. The patient is a woman 43 years of age, has had four children, three of whom are living; family history negative; first noticed the disease eleven years ago when menstruation ceased and a constant constipation commenced, which is relieved only by a very active cathartic. Headache is constant, always occipital, sometimes referred also to the top of the head near the anterior fontanelle, and about the size of a silver dollar. Memory is very poor; somnolency present. The tongue is greatly enlarged, also the tonsils and some of the adjacent tissues and a tickling sensation present there. There is typical condition of the hands and feet, enlargement of the head, pronounced prognathism, numbness in extremities, tactile sense impaired, urine normal, great thirst, good appetite; thyroid gland not enlarged, and no thoracic thyroid to be found. Kyphosis is present, also joint pains. Height, 5 feet; previous weight, 130 to 135 pounds; present weight, 186 pounds. Wore No. 4 shoe formerly, now a No. 7 man's arctic. Chest measure forty-one inches. Eye symptoms: Lids thick and edematous; conjunctiva and cornea normal; lachrymal apparatus normal; pupil normal in size but sluggish in action. Partial atrophy of both discs; veins congested and arteries small and pale. Retina normal, as also action of muscles, though very slow to demands of will. Field of vision, as shown by a perimeter in which colored lights were used, shows

bilateral temporal hemianopsia in white, blue, red and green fields. Right vision 10 200; left vision, 10 20. In from 45 to 50 per cent. of the cases eye symptoms were present. Since 1890 there have been reported twenty-one cases of bilateral temporal hemianopsia. One case of homonymous hemianopsia has been reported by Sir William Broadbent. A number of autopsies have been reported. Probably the most thorough one is that reported by Dr. Osborne, who is inclined to the opinion that the disease is due to lack of function in the pituitary body. In my case the wrist measures eight and a half inches around, and the ankle fifteen inches. The sternum and intercostal cartilages are enlarged. Kyphosis is almost always present.

Dr. WARE—I saw one case a number of years ago with beginning atrophy of the optic nerve, the result probably of bone pressure, as the bones of the skull were thickened and enlarged.

Dr. WESCOTT—I examined the case some years ago as to the eye symptoms and found some narrowing of the fields with partial atrophy of both nerves. The patient was sent to me because of constant headache. Glasses were of no benefit.

Dr. PINCKARD—I have seen three cases and none of them had any subjective symptoms of eye trouble.

Dr. LAWBAUGH—This is the fourth case I have seen. One had temporal hemianopsia in the right eye with total atrophy in the left. But the other two presented no eye symptoms at all.

Dr. COLEMAN—I have seen two cases similar to the one reported by Dr. Lawbaugh. One, a young woman 22 years of age, had bilateral temporal hemianopsia, but suffered little inconvenience from it. The second case was a man 75 years of age, who had right temporal hemianopsia with contracted field for all colors. Vision was 20 40 in one eye, the other being imperfect for many years.

Dr. LAWBAUGH—Benson, in the *Dublin Medical Journal*, reports a case of bilateral temporal hemianopsia with acromegaly in a man who was a drinker and smoker, but after dropping these habits the normal field of vision was regained. Benson attributed the symptoms to pressure on the chiasm, the tumor being increased by these poisons, and upon their cessation the normal size of the pituitary body was restored and the pressure relieved. He afterward resumed his old habits with resulting atrophy in one eye and temporal hemianopsia in the other.

Dr. WESCOTT showed specimens from a case of primary carcinoma of the conjunctiva. An examination made by Dr. Hektoen showed the tumor to be a carcinoma growing from the epithelial layers.

C. P. PINCKARD, Secretary.

103 State Street.

Associated Health Authorities of Pennsylvania.

Fifth Annual Meeting held at Lancaster, Pa.,

May 18 and 19, 1898.

(Continued from page 1461.)

FIRST DAY—AFTERNOON SESSION.

After the report of the Executive Committee, urging an effort to obtain a better representation from the boards of health throughout the State, Prof. J. N. RODDY of the Millersville School read a paper entitled

WEATHER FORECASTS AND HEALTH.

He said: There are two great fields of human knowledge: in one we seek truth for its own sake, and all honor should be to him who enters the field, for man is slow to reward the discoverer of pure truth as he merits. In the other sphere we are seeking to bring knowledge into relation with things. This is the application of knowledge to practical uses. In this experimental application of truth modern science has accomplished wonders for mankind. It has increased his earning capacity many times over. In no application of scientific method has more advance been made than in the treatment of disease; in sanitation, or in the creation of healthful hygienic conditions. Almost every department of knowledge has been made to contribute; new departments of investigation have been inaugurated. Hence it is somewhat of a surprise to find that little has been done in the way of experimentally tracing the relation of local weather conditions as well as general climatic conditions to health. It is especially desirable here in America that we seek the cause of whatever relation exists between weather and health, since we live under very unequal weather conditions. Moreover, weather does not come in homeopathic doses, but when a blizzard, a warm wave, or a cyclone strikes us, no one could desire a more generous portion. We all appreciate the fact that certain diseases lie in

belts mainly within certain isothermal or temperature limits. Yellow fever fluctuates back and forth over the equator with temperature changes. Smallpox is a winter disease dying out with the increase of heat. These statements express not the reasons for the relation but simply a relation in very indefinite terms, because no one has even partially investigated all the conditions favorable or unfavorable to the propagation of the germs of these diseases. To obtain a concrete conception of the relation we know in reference to weather changes and health, and to personal comfort, we must express the laws upon which forecasts are based. Weather seems fickle but at the same time is subject to rigid law. The fundamental elements of weather changes are high and low pressure areas produced by heat and cold, mainly. Another fundamental element is moisture in the form of vapor distributed through the atmosphere in ever varying quantities, relatively. There are great varieties of topographic features making up the land surface of the earth, and many kinds of soils. When these receive the sun's radiant energy they are heated to different degrees, and hence the area most heated becomes by the uplift of air over it and the consequent outflow at the top a place of low pressure, while surrounding regions receiving the outflow of air above become areas of high pressure. High pressure areas may result from excessive cooling and consequent inflow of air. Since the air whirls in or out low pressure areas are cyclonic and high are anticyclonic. Humidity conditions may enter as a factor in making the highs and lows more equable. It follows, therefore, that in summer as the result of the great excess of heat on the land masses over that of the sea that low pressure areas predominate on the continents and highs on the ocean. The reverse is true in winter. These relations are an uninvestigated question. We may suggest certain theoretic problems. Every low, in consequence of the exhausted condition of the air, may contain much vapor and therefore be deficient in the essential to life oxygen. Lows in consequence are depressing and we would infer that care should be exercised as to skin conditions, in diet, and against over-exhaustion. The blood is necessarily not fully oxygenated and the digestive functions are in consequence not so vigorously performed; nervous energy is lacking; the tone of the body is low. This is theoretic, yet records show the greatest number of suicides under these conditions of low pressure and high humidity. Whether this be a coincident or a sequent relation, we need to investigate. With high barometer and low humidity there is greater abundance of oxygen; skin and lungs act vigorously; oxidation is rapid, the body demands more food and we feel buoyant. Nervous energy is in excess. Might we not under these conditions overrate some organ and suffer in consequence?

Every area of low pressure is an area of precipitation and an area toward which the wind blows from all directions. Every area of high pressure is one from which the wind blows away in all directions and the latter is also calm and clear. It is also a law of weather that in one zone the prevailing winds are westerlies. These prevailing push all weather areas across our country toward the east. If a low pressure area starts in the west it crosses the continent bringing with it some form of precipitation, storms, and higher temperature than usual. This low will be followed by a more or less developed high, bringing reverse weather conditions. From these laws it would seem to follow that we can prepare ourselves by proper clothing, proper food, prudent diet to withstand these changes and keep in perfect health. We do not regulate ourselves as the waves of so-called grip following in the wake of certain classes of storm indicate. The greatest and perhaps the most sudden fluctuations of weather are experienced in some of the New England States, and especially is this true in the changes in temperature and humidity. Corresponding with these sudden changes it is said by good authority that there are more pulmonary affections here than elsewhere in the country. Again, whether this is a direct resultant of the weather changes, or of other hygienic conditions, we as yet do not know, but it proves the necessity for thorough investigation. Not only do we experience the alternations of pressures and humidities, but also of alternating winds when an area of high or low pressure passes us. Suppose a low pressure area to be west of us, we will then experience east winds until the area of low pressure reaches us, when the winds will have reached their greatest velocity from the east and precipitation in some form has attained the maximum. When the low pressure, which we may term a storm center, passes us going eastward the wind is reversed, blowing with great velocity and bringing clear and cool or cold weather. Since the winds do not blow straight in nor straight out from the storm center, they are termed cyclones or anticyclones. In winter they invariably result in blizzards that cross the United States in about two days and

often bring with them a rapid fall of temperature amounting in many cases to 40 or 50 degrees, and in northern Texas to 60 degrees. Over our continent in summer, storms of the same character sweep bringing in their wake westerly waves, dry, dust filled, warm air called hot waves with rises of temperature as much as 20 degrees. Each of these is predicted by the weather bureau and announced at least twenty four hours ahead of the storm. It follows that these sudden changes in temperature, winds and humidity will affect us if we do not prepare for them, and since many of the diseases have their inception in common colds and since a cold is a mechanical condition of the pores of the skin in which the pores are simply closed by sudden chilling, thus throwing greater work on the other excretory organs, that some attention must be paid to clothing and food and perhaps mental condition. We need greater attention to these changes, a better appreciation of the laws, and subsequently a greater knowledge of the relation of weather changes to bodily conditions. In a series of experiments recently made by the Smithsonian Institution on the questions of external temperature, clothing and bodily temperature inside the clothing, several curious results were noticed. One was that there is no correspondence between our bodily sensations and the actual external temperature. It often followed that when the temperature was quite low the body did not feel correspondingly cold and *vice versa*. It was found that there is a fairly constant relation between bodily sensation and the humidity. With high humidity we suffer more from cold than when the air is dry. The reason is almost self-evident. Bodily functions are performed slowly when the air is full of moisture, because of the lack of oxygen and the partial failure of the skin to perform both its excretory and absorbent functions. The body soon clogs. Heat is not generated. Colds very easily result.

One of the strange meteorologic phenomena of our country is the magnetic storms. These, moving somewhat like a cyclonic disturbance, often move across the continent from the west to east. They also have an effect upon us in some mysterious way. Patients suffering with neuralgic or rheumatic affections find these storms intensify their pains and that wave like movements of the pains occur. This perhaps indicates some relation between nerve centers and magnetic conditions. Cyclonic disturbances which usually develop electric conditions of the atmosphere also produce these effects, but with less intensity. This leads us to say that we all desire the greatest possible personal comfort which tends to longevity and therefore highest mental efficiency. We secure this by careful attention to dietetics, efficiency of clothing and weather conditions. Finding that bodily sensations are deceptive, should we not regulate our lives more scientifically than we have in the past, more by the thermometer and barometer readings daily furnished us by the weather bureau? The daily isotherms and isobars furnish us the general conditions by which we may judge of the weather and to these our own observation and reasoning must furnish the requisite supplements to furnish local forecasts. In view of all these facts it becomes almost imperative that we institute investigations on the relations of high and low pressures to skin functions, to oxygenation of the blood and to digestive functions; so too with humidity. A large field is open for investigation on clothing in relation to personal comfort, healthfulness and the preservation of equable temperature for the body. At the same time it must not be forgotten that magnetic storms and their influence upon us need attention. I believe such investigations will well repay us in giving a better understanding of our relation to climatic conditions.

THE BUBONIC PLAGUE

was the title of a paper by Dr. BENJAMIN LEE, Secretary of the State Board of Health of Pennsylvania. He said: A plague is a wide-spread, virulent, epidemic disease; a pest or pestilence. One disease of this nature, however, is so pre-eminent above all others in point of malignity, destructiveness and horror that by common consent it has obtained the designation of "The Plague." The word signifies "stroke" and is a survival in our language of the belief of a superstitious age that an epidemic was the "stroke of God," the conscious vengeance of an angry deity, thus making the Almighty responsible for the inevitable results of our infractions of the simplest laws of nature, or, as has been well phrased, "haunting our filth in the face of the Deity." It has also been denominated the "Oriental Plague," because it has always originated in the East; the "Egyptian Plague," because for a long period, comprising the last century and the early part of the present, it was never absent from Egypt; the "Levantine Plague," because it has prevailed in all the cities of the eastern end of the Mediterranean Sea, and the "Bubonic Plague," because

one of its marked characteristics is the appearance of glandular swellings or buboes in various parts of the bodies of its victims. Under the name of "Black Death" it is estimated in the course of five years, about the middle of the fourteenth century, to have carried off 25,000,000 people, or one-fourth of the entire population of Europe. London, Marseilles, Toulon, Florence, Moscow, Transylvania, Venice, Lyons, Paris, Avignon, all have their fearful records of its devastating horrors. With the march of civilization and the adoption of personal, domestic and municipal hygiene, it has, however, been crowded back into the domains of the filth loving Asiatics with whom it originated, having last invaded Europe on the lower Volga in Russia nineteen years ago.

In certain regions in China, and in the Valley of the Euphrates, it has never ceased to exist. Since 1873 it has constantly prevailed to a greater or less extent in the province of Yunnan, China, and for more than twenty years has been present in the city of Pakhoi. In February, 1894, it showed itself in the city of Canton, spreading with such rapidity that in the space of three months the number of deaths ran up into the tens of thousands. By the month of May it had reached Hongkong, ninety miles distant. It is from the careful and intelligent report of James A. Lowson, M. B., medical officer in charge of the Epidemic Hospital of that city, that we gain our definite knowledge of the disease as it appears during the present outbreak. Previously to this the only exhaustive and scientific study of this disease which had been made was the report of a committee of the Royal Academy of Medicine of France, made in the year 1846. This committee devoted two years to its work and, while it carefully sifted such histories as were available of the various European outbreaks in past centuries, it derived the greater part of its information from medical and official eye witnesses of the great epidemic in Egypt in 1835. Making allowance for the advance made in our knowledge of the causation of epidemic diseases during the intervening half century, we find a striking correspondence in the results. It is interesting to note that even at that day a member of the Academy, Bosquet by name, during the discussion which followed the reading of the report, announced his belief that the cause of the disease was a germ, and formulated the statement, remarkable in the light of modern discovery, that "every contagious disease creates a germ capable of reproducing itself." That which in his day was theory, and for announcing which he was ridiculed, has today become fact through the researches of a distinguished scientist, a native of a country at that time almost unknown, but since thrown open to the light of civilization by the action of the Navy of the United States, the Japanese physician and bacteriologist, Kitasato, to whom belongs the distinguished honor of having first discovered the bacillus of this dread disease, a discovery second only in importance to that of the germ of Asiatic Cholera by the immortal Koch.

From Hongkong the disease was conveyed to India, evidently by ships, making its appearance in Bombay in August, 1896, but its presence was not officially acknowledged until the physicians had recognized it for a month; much valuable time was therefore lost. In this city it raged for months with a virulence that was truly frightful. The facts of the Bombay visitation bear out in a very striking manner the history of the plague's ravages in the Middle Ages, when its victims were largely among the indigent and ill-fed classes. The outbreak in Bombay first occurred in one of the most equid quarters of the town, and with certain exceptions it has spared the wealthier classes. Englishmen, whether through a transmitted immunity which they have shared with the nations of Europe since 1841, or from a higher standard of living or from whatever cause, have enjoyed a freedom from attack so remarkable as to render isolated cases among them quite phenomenal. While the mortality from all causes ran up to sixty-three per thousand at the beginning of November, and again to sixty-three per thousand in the third week of that month, the general death rate among the well fed Parsees was just under thirty, among the even better fed Europeans twenty-four, and among the amply fed European community only eighteen per thousand. But among the filthy low caste natives the mortality was appalling. For weeks the deaths from plague alone numbered more than two hundred a day. Huge flocks of vultures hovered all day long over the "towers of silence" where the bodies of the Parsees are laid out on an iron grating to be torn to pieces by these unclean birds. In the Hindu burying ground graves could not be dug fast enough, and the Mohammedan cemetery is described as having presented the appearance of a battlefield. All night long the funerals wound their melancholy way through the streets, preceded by priests with flaming torches, breaking the midnight stillness with the discordant clashing of cymbals, and the weird dirge, "Ram sri

ram, Ram bolo bhai ram," to the accompaniment of the mournful wail of long twisted horns.

The disease may be briefly described as an acute febrile infectious disease, characterized by a tendency to buboes or suppurating lymphatic glands and carbuncular swellings in various parts of the body, marked cerebral and vascular disturbances and intense prostration.

It is due to a specific germ, a bacillus or short rod with rounded ends, which has been found in the blood and glands. Infection takes place through the lungs, digestive canal and wounds or abrasions of the skin. The period of incubation is brief, often less than two, rarely more than six, days. The death-rate is higher than that of any other known disease. About eighty out of every hundred stricken die, and the course of the attack is swift as well as sure and fatal, death usually occurring on the second day. If the patient is going to survive, symptoms of improvement begin to show themselves between the sixth and tenth days. No treatment has yet had any effect in reducing its mortality. Much is hoped, however, from an antitoxic serum similar to that used in diphtheria.

One very curious feature of its approach is that it attacks rats before it attacks human beings. These creatures come out of their holes to die, evidently in a state of delirium, as evidenced by their losing all fear of man. This would lead to the supposition that the germ grows in the earth, spreads along the surface and is not communicated through the air. This theory is also supported by the fact that certain localities become infected while others not far distant remain entirely free from infection. In this respect there is a striking resemblance between the mode of propagation of plague and yellow fever. This latter disease will sometimes prevail on one side of a street while those living on the other side are entirely free from its attacks. All the domestic animals are liable to this infection. Dogs, rats, hogs, buffalo and other horned cattle, and domestic fowls have all been known to die of it in great numbers. As all of these creatures browse or feed upon the ground, this fact gives additional support to the theory advanced.

The conclusion which we arrive at then is that this affection is not contagious in the strict sense of the term, not conveyed from person to person, but infectious, clinging to places and things, the earth, houses, ships, furniture, bedding and clothing, and developing its deadly qualities in such situations outside of the human body. The question may naturally be asked, Is not this subject rather one of curious interest than one of practical importance? Why waste our time considering a disease which has never been seen in this country and is never likely to be? To this I reply that there was a time when neither scarlet fever nor diphtheria had ever been seen in this country, and that within the present century. It is well known that the early settlers brought smallpox to this virgin land among the other blessings of civilization, and that under its blighting influence the aborigines, if they were such, melted away like snow before the sun. Plague is most readily conveyed in ships, and when once the soil of a country has had the seed sown in it, the weed becomes most difficult to eradicate. The following incident shows that this danger is a real and not a mere fancied one.

On July 16, 1897, the British ship, *Annie Maud*, arrived at the U. S. Quarantine Station, Angel Island, California, having lost one of her crew from bubonic plague during the passage from Calcutta. Two more of the crew were seized with the disease but recovered. Under the careful system of disinfection pursued by the authorities, the infection was destroyed, but the incident is significant as showing with what ease the disease may be brought to our shores. The energetic health officer of the Port of New York was thoroughly justified in taking the precaution to disinfect all the mails from plague stricken districts in India. Everywhere in Europe the most energetic measures were taken to prevent the introduction of the disease through vessels or cargoes arriving from East Indian ports. We can not rely on climate to protect us from its invasion, as during the present century even it has been seen as far north in Europe as Moscow and points in Norway and Sweden.

Impressed with a sense of the responsibility resting upon them, in consequence of the frightful ravages of this disease in India at that time, and its evident tendency to spread westward, representatives of the State Board of Health, of the Board of Health of the City of Philadelphia and of the State Quarantine Board, met in conference on Jan. 23, 1897, to discuss the possible invasion of the disease, and the provisions which should be adopted to prevent such a calamity. A certain line of action was determined upon for each of these bodies in accordance with their respective powers and duties. The leading spirit of this little assemblage was Dr. Wm. H. Ford, then President of the Board of Health of Philadelphia, whose useful career was in a few short months so abruptly cut off. I can not better close this paper than by offering a brief

and altogether insufficient tribute to the memory of that devoted Christian gentleman, faithful public officer and distinguished sanitarian. All the best years of his life were devoted unstintingly and without compensation to the good of his community. To him in great measure is due the admirable efficiency of the Board of Health in that city. Those of you who have been in the habit of attending these meetings will distinctly recall his noble personality and the wisdom of his words. At that conference he made substantially the following statement in regard to the possibilities of the arrival of the plague on these shores and the means which should be used to prevent it from finding a lodgment:

What concerns us most on this continent is the use of preventive measures. As it has been proven over and over again that this disease no longer occurs in countries where the people are prosperous and enlightened and rigid in the enforcement of sanitary measures, the prospect of the disease gaining a foothold in this country or of even gaining admission through our quarantine stations is extremely unlikely. Nevertheless, the wise man is never self-satisfied, but always on the alert and prepared for any emergency that may arise. Our quarantine defenses are, as a rule, excellent, and the officers in charge fully alive to the necessity of constant vigilance. As the disease prevails under faulty hygienic conditions, the obligation of the municipality is to remove all such faults and place the city in the best possible sanitary condition. Domestic and public cleanliness is the barrier to this and all other dangerous communicable diseases. The public management of the plague is the same as we are accustomed to enforce with regard to contagious and infectious diseases generally, and consists primarily and fundamentally in isolation and disinfection. A people prosperous, enlightened, progressive and scrupulous in the application of well-known hygienic measures need have little fear of the oriental plague finding a lodging place among them.

Dr. T. S. LIPPINCOTT of Hoppenville read a paper entitled

WHAT MEANS SHOULD PROPRIETORS ADOPT TO PREVENT THEIR REFUSE FROM BECOMING A NUISANCE?

He wished to present some insanitary facts relative to the various creameries. In September last my man commenced to deliver milk to the creamery and as is customary with all its patrons (the farmers), all fill their empty cans with slop which they take home for hog feed. It is generally understood on the outside that the farmer who sends his milk to the creamery gets skim-milk in return, but when it comes to reality, they are only entitled to the slop out of the outwells where all refuse of the creamery is conducted. This is exposed to all kinds of weather, but nothing affects these wells as does the sun and hot weather, as they are never covered, nor cleaned out, having run in them each day skim-milk, water, dirt and washings from the building and utensils. This decoction also came home in our milk cans. Imagine my surprise when my man emptied the return cans of slop, which was the foulest as to odor. Not unlike the worst kind of a water-closet, or human excreta. After a few returns of this kind, finding it to be a perpetual thing, my man refused to wash the cans, and no one could blame him. Yet the farmer continues to carry this home and feed his hogs with it or let them starve. This is not only so of one creamery, but all over the State, and with our experience after washing the cans, they retained the filthy odor for days, yet the farmers fill the same cans in the evening with fresh milk for the next trip, day after day. From the milk comes the butter to our tables, and I am informed the State Board of Health is unable to remedy this evil for lack of legislation. While little Jersey is prepared to meet and correct any such insanitary matter, imagine my surprise when I wrote to Dr. Leo and suggested that he send an inspector, whom I would aid in his work, and he informed me that this great Commonwealth had no such person to send. If our bacteriologists are looking for a fertile soil for bacteria, a visit to one of these wells on a hot day would furnish all he could desire. After several inspections of these places, I suggested an easy means of correction, an outlet making it a flush well. They reply it is time enough when such things become a law; so the evil goes on. We have a mass of statistics tracing bacilli to milk and it is to be hoped that this Association will agitate this matter till we have laws similar to those of New Jersey.

A free discussion followed and on motion it was referred to the Committee on Legislation with instructions to draw up an act and submit it to the legislature.

Under the head of voluntary contributions, questions, etc., Dr. Crowther brought up the subject of milk inspection. It was shown that wherever there was milk inspection, improvement invariably followed. The whole milk question should not be in charge of the Department of Agriculture as at present, but in the hands of the Board of Health of the State.

As the Committee on Legislation was yet to report, this matter was postponed until that had been heard.

Dr. THOS. TURNBULL of Pittsburg offered a resolution from the Sanitary Bureau of that city, urging legislation permitting the medical colleges to give diplomas for Doctor of Public Health to such students as had completed courses in hygiene and kindred sciences. Such persons should be preferred as medical inspectors for all boards of health. On motion the resolution was adopted.

FIRST DAY—EVENING SESSION.

The Annual Address before the Board of Health was given by Dr. J. T. ROTHROCK, State Commissioner of Forestry, on

SANITARY RELATIONS OF OUR HIGHLANDS TO THE STATE.

It was illustrated by means of the stereopticon showing the results of the destruction of the forests throughout the State.

He said: Civilized man has reached his present condition by a series of steps, which in all countries show a general resemblance, modified by the surroundings known as environment. Originally labor was the lightest: he sought the lands which gave large crops with little preparation: preferred the level, bottom lands; only went to the mountains for chase or from necessity. As to changing the character of the country, his influence was about that of the beaver. New needs, commercial relations, pressure of the population brought the duty of invading other fields and seizing resources previously untutilized. Soon he became aware that he was a machine, subject to wear and tear, ills and aches, resulting from location, and he was compelled to act accordingly. We all know men who are conscious of danger, but lack the mental keenness to take the necessary steps to avert it. All know regions having pre-eminent salubrity, and of small value for other purposes. These should be devoted to sanitary purposes. This raises the relation of the commonwealth to its population. The State should protect itself, provide for its perpetuity. Hence we have no right to despoil the estate of the future, but leave it in as good a condition or better than we found it. We are a chosen people only so long as we obey the moral and political laws. We have no right to render any region less healthful. No business interest has the right to injure the land so as to make it unfit for the people. We strike at the power of the commonwealth. There is State charity for the sick or injured, lame, halt or blind, insane, etc. The fruit grower is to be protected against diseases which invade his orchards, but what affects the vitality of the race is so little prevented that it is nothing. Tuberculosis must not in the future menace others. The State must interfere. The world advances faster than any one of us, and soon we become back numbers. It is over forty years since I began to observe the character of the various portions of the State. When I began, there was an area of say 8000 miles nearly in the center of this State almost a continuous forest. One-sixth of the State was in its original condition. Now hardly a vestige remains. The axe and fire have destroyed it. But one or two original forests of any size remain in the State. Now, if woodlands have any hygienic relation to the commonwealth, is it not time for protection to be given? Unfortunately these lands have no agricultural value; desolation is everywhere. In looking at the Adirondack region of New York, healthfulness stands pre-eminent; it is a standard. The pulmonary death-rate is 1 in 854 to 985 of the population. This is a great advance from 1 in 400 of the population in the regions adjacent to New York City. In the seven southern counties of New York, the rate is 1 in 1091. In McKean county of this State, the rate is 1 out of 1330. In thirteen years, 1881 to 1894, in Philadelphia, the rate from consumption has decreased almost 31 per cent. But as we can hardly anticipate a time when it will be as low as McKean county, that will stand as a comparison. Now if hospitals were located there the patients would have the advantage of every favoring condition. Of the hospital appropriation of this State, \$843,800, only \$18,000 were spent in the counties of Warren, McKean, Potter, Tioga, Bradford, Susquehanna, Wayne, Pike, Sullivan, Cameron, Elk and Forest. These twelve counties, endowed by nature with an exceptionally healthful climate, with a population of one-fifteenth of the entire State, receive about one-forty-seventh of the appropriations of the commonwealth. The inference is that because of the very healthfulness they possess they are to that extent free from the necessity for a more equitable division. Again, we are informed that the region is one exceedingly favorable for those afflicted with pulmonary troubles, and here we have a natural sanitarium equal to the Adirondacks. From the time of the early Aryans, men have longed for the freedom and rejuvenation of the woods. People who have lost their fondness for the woods have lost their virility. Pennsylvanians spend thousands of dollars annually in the Adirondacks, mainly

because we have destroyed the primitive attractiveness of our own woods. In the above counties there are large areas where agriculture is impossible, and even grazing gives but slight hope of becoming remunerative. Much of it is abandoned, and later will come into possession of the State. Protective fire laws will in all probability be enacted and allow restoration of the primitive growth. This area can be turned to no better purpose than that of a State Forestry Reservation, the property of the people, dedicated to them and administered for the good of the whole people. Here sanitariums will be located. He quoted the bill of New York for the establishment of such places and hailed it as an omen of the future. The Rush Hospital of Philadelphia is the only one in our State for consumptives. This year it received \$5000 from the State, and is one of the forces working for better means of dealing with this disease. Abroad, all lead us in this care for consumptives. Recently, Dr. S. W. Trimmer has given, free, a lot of land favorably situated near White Haven for the erection of a sanitarium for consumptives. It is the starting of a great movement which promises to commend itself to the citizens and legislators. The ground is high, air pure, railroad access easy, and delightful drives will tempt the patients out into the open air. He alludes to three cases of this disease which made a deep impression on his mind: one a physician who had become so weak from tuberculosis as to be unable to work. On a raw day in March he accompanied the speaker in a drive thirty miles to a highland in Sullivan county. A snow storm came on, the man became exhausted when they reached the hotel, and it seemed doubtful if he could rally from the condition into which he had fallen by the exposure. He was put to bed in the hotel, restoratives employed, rallied, gathered strength daily, in six weeks went back to his profession, until the following spring when he again declined. He was sent to Cuba, no good followed, and he died in a few months. The speaker believed that a residence of a year in the North Mountain region would have prolonged this valuable life. Again, a geologist resigned his duties, sought health in the field, was assigned to a government position in the Rocky Mountains. In ten days he was sleeping on the ground in the open air, at an altitude of 12,000 feet. In June the air was still raw and masses of snow lay unmelted near the camp. In November when he rode his mule into Denver the thermometer was below zero, but he returned to New York with a gain of twenty pounds of flesh. He lives today, one of the honored scientists of the land. Again, a private soldier with a diagnosis of consumption, received no special treatment, and was assigned to duty; as summer wore away he gathered strength; in autumn, after more than five months of active field service he returned with his company, rugged, hearty, with a gain of thirty-five pounds. Now, while the invalids in Colorado breathed the same air at night, they were stowed away in more or less stuffy rooms, robbed of half the benefit which should have been derived from proper protection in the open air for twenty-four hours each day. Of course, we must have a fair recuperative power left, or it can not be successful. We should have protection so as to burn up the minimum of tissue in keeping warm. He alluded to the soldiers just now leaving, tenderly reared, thrown into camp, short of food, etc., yet while one might have expected a fearful amount of sickness, the list is very small. Is it not time for us to act in accordance with what we are shown; let all invalids have the open air, with proper protection, etc., and thus save many valuable lives for years. The pine woods of Minnesota have lost much of their value since the loss of the covering of timber. Pneumonia is more common; tuberculosis also, thus showing how guilty we are. Remember that pure open air is the important need. Summing up, the State highlands show a small percentage of tuberculosis as compared with other regions. They are in a large measure unfit for remunerative agriculture; are mostly stripped of the timber, the only crop for which they are fitted. Fires have destroyed the young timber. The soil is reverting to a desert condition on which no crop can be grown, even of trees, except at great expense. In the near future they will be a source of injury to the commonwealth. They diminish the productiveness of the soil by removal of the moisture, and increase the virulence of disease germs by concentrating them in a smaller volume of diluent. The State must assume control. Such areas would become the home of natural sanitariums, and nearer home than the Adirondacks. The fact does not appear to be recognized that there is an almost continuous belt from Pike to Forest county, with an altitude of 1200 to 2300 feet above the sea level, and one may find in it during the summer a temperature seldom above 80 degrees, and at night one may sleep with comfort under blankets. Again, while in the East the coast people suffer from east winds, these regions enjoy a more seasonable and comfortable climate. There re-

mains one point. Lord Kelvin, the scientist of England, called attention to the subject, "Is the Air giving out?" He thinks the oxygen is depleted beyond the power of plants to replace it. While at the same time plants are being destroyed, every forest destroyed is an oxygen factory destroyed. There is great pertinency in this point. In the near future our supplies of water must be changed all over the country. The wells are affected by disease germs. We will be compelled to go to the fountain head for water; but if we continue to destroy our trees the sources will be lost or greatly diminished. A mile square of surface will give to the sun in July not less than 3,229,304 gallons of water. If this amount could be saved, if we simply kept the fire off the ground, allowed the soil to cover itself with timber again, we could save this. Remember the average citizen is not fit to control the conditions upon which the water-supply depends, so we must ask the Government to give us such legislation as will enable it to be controlled. Delay is costly. We must act at once. Neglect a little longer and we can never reclaim the lands thus denuded. From just such unproductive highlands the German government is now deriving a large part of its income, by the production of timber. But this is not all. In the Black Forest a German student will spend a whole vacation gaining health, strength and knowledge, for a smaller sum than one of us will spend in a fortnight in one of the ordinary Adirondack resting places. So it might be here. But the wholesome life of the German forest villager or student at present finds little encouragement on desolated hillsides. We owe it to the future that this condition of affairs be changed; that the diminished volume of our streams in summer be restored to proper size; that 6000 miles of the area of our commonwealth be changed from areas of evaporation to become water-retaining surfaces, because the agricultural world is fast coming to the conclusion that the certain growth of crops will soon force the need of irrigation upon us here. Further, we need that these areas be made productive of forest wealth for our industries, and health for our ailing citizens. We have a right to demand that an end shall be put to the annual scourges of fire which turn to smoke and ashes the wealth of the State and the property of its people. We may confidently hope that the law will intervene and prevent that misuse of natural resources in soil upon which depend so largely the life and strength of the State itself.

PRAGTICAL NOTES.

Essential Asthma Cured by Compressing the Pneumogastric.—Encouraged by his success in arresting paroxysms of coughing in pertussis by compression of the pneumogastric in the cervical region, as already mentioned in the JOURNAL, Miranda has accomplished the same results in severe attacks of asthma in subjects with pronounced neuro-arthritis. The patient himself or his family are easily instructed how to perform the compression. He reports four cases thus treated and cured; in each the nervous element predominated.—*Semaine Méd.*, May 18.

Dry Dermatitis.—According to the *Pennsylvania Medical Journal*, the toxic principle of poison ivy (*Rhus radicans*, L.) is non-volatile and, on the authority of Dr. Franz Pfaff of Harvard University, a fixed oil, which he has named toxicodendral. Alcohol dissolves it readily and alkalies readily saponify it, but the best of all applications is an alcoholic solution of lead acetate. Other popular remedies, *e. g.*, fluid extract of grindelia or serpentaria, doubtless depend upon the alcohol which they contain. An objection of the *Medical World* is that local applications of alcohol alone do not suffice without the grindelia or serpentaria, and a preference is given to the sweet spirits of niter full strength or diluted one-half.

Weiss's Treatment of Cephalalgia.—Weiss has endeavored to investigate this subject in the light of personal experiments and of physiologic review of the anatomy of the brain. He said it was usual to divide cephalalgia into angiospastic and angioparalytic, often described by Benedict as hyperesthesia of the scalp and cranial bones where lightning and hammering pains were present. These symptoms were usually associated with an irritation of the sympathetic, and most of our thera-

peutics have been directed to a modification of the circulation in the brain. Here and there electricity may relieve the pain, but compression on the carotid was without the expected relief. He was now of opinion that compression of the aorta in the abdomen between the xiphoid process and the umbilicus immediately removed the cephalalgia, which it had successfully done in twenty-three cases. On a former occasion he had described the action of this abdominal compression as being transmitted through the sympathetic, but he was now of the opinion that the compression of the aorta, acting on the blood supply, was the principal factor in the phenomena. These observations require further elaboration, as the pain in the head is only temporarily affected, and not cured.

Invariable Presence of Pneumococci on the Surface of the Tonsil.—Bezançon and Griffon have laid before the Paris Hospitals Medical Society the results of some researches which they had made on the presence of the pneumococcus on the surface of the tonsil. In place of using inoculations *en masse*, after the method of Netter, they employed a culture-medium specially fitted for the pneumococcus, namely, the serum of a young rabbit. It is generally admitted that the pneumococcus can be found in the throats of healthy individuals about once in five times, but according to these observers this is a wrong proportion and due to faulty technique in the examination. The pneumococcus may exist constantly as a saprophyte in the same way as the streptococcus. If up to now the pneumococcus has not been found in more than a fifth of the cases examined it is easily explained by an alteration in the method of cultivation, the method of culture being for choice by taking some of the tonsillar mucus and not simply the saliva. The forty individuals examined by them were of varying ages and kinds, quite young children, adults, old men, some taken from a hospital atmosphere, some from laboratories and some living under circumstances from which any source of contamination could be reasonably excluded. In none of these patients was there any history of pneumonia. The only conclusion which can be drawn from these facts is that its organism is found in a great variety of diseases.—*Lancet*, April 30.

Hints for Asepsis; Gloves and Hoods.—Avoid all contact with septic things. Use scissors and forceps in removing dressings, never the fingers, and always moisten them beforehand with warm salt solution, preventing infection of the fingers with dry floating particles. If the fingers must be used, rub them well with vaselin and cleanse and disinfect them at once afterward. Operate dry. Have the instruments lying ready on dry aseptic cloth, after having been boiled in soda solution. If they become smeared with blood it is not necessary to remove it unless it interferes with the operation, when they should be laid a few moments in boiling soda solution, which should always be at hand. The above suggestions are from an article in the *Munch. med. Woch.* of May 10, by Berndt, who adds that aseptic silk thread is less harmful to the tissues than antiseptic, as its injury is only mechanical. Vulpius, in the same number, asserts that he considers the Lisle thread gloves of great assistance in securing asepsis during operations which are not liable to be flooded with blood, as the gloves keep the hands sterile as long as they are dry. They are especially useful in orthopedic operations on the extremities. He also uses a hood or capote, with no opening except for the eyes, for all operations, except very long ones (when they would become oppressive), calling attention to the "rain of bacteria" that follows the accidental brushing of the operator's head against that of an assistant. Still another precaution is the covering of the surface around the field of operation with an impermeable cloth before laying the sterile compresses around to wall off the field. He has found that if these sterile compresses become moistened with dripping water or blood during the operation they suck up germs from the skin beneath, which is prevented by the impermeable covering.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JUNE 25, 1898.

STENOSIS AND OBLITERATION OF THE AORTA IN THE VICINITY OF THE DUCTUS BOTALLI.

EMIL WADSTEIN¹ has collected 113 cases of stenosis and obliteration of the aorta in the vicinity of the ductus Botalli; of these five are new cases. Ten of the total number are purely clinical cases, in which the diagnosis has not been confirmed by postmortem examination. In order to obtain a clear notion of the normal conditions, so as to be able to differentiate between a physiologic and pathologic narrowing of the place in question, the author also examined the aorta of 105 children, whose ages varied from newborn to three years.

With respect to the pathologic anatomy of this condition, then narrowing may occur in all possible degrees to atresia, which was present in twenty of the cases. The maximum degree of narrowing was found to be situated above the duct of Botalli in 16.4 per cent.; at the point of the duct in 38.8 per cent., and below in 44.8 per cent. Occasionally the narrowing may be double. The microscopic examination in one case showed the following changes in the wall of the aorta:

Both intima and media were very considerably thickened at the point of stenosis, and at the same time there was considerable disturbance in the normal histological structure, consisting in a thickening of the innermost layers of the intima, together with the presence of occasional bundles of connective tissue, which passed directly through the membrane. The media contained a larger number of smooth muscle cells, which formed a ring immediately under-

neath the intima and directly opposite the narrowest point of the stenosis.

Arterio-sclerosis of the aorta occurs in about every third case of stenosis. The average age of the patients in these cases of arterio-sclerosis was found to be only 35.7 years; in two cases the age was only 17 years; in three cases 19 years, etc. Arterio-sclerotic processes are most pronounced proximal to the stenosis in the majority of cases; then directly opposite the greatest point of narrowing; and least often distal to the stenosis. The author looks upon this distribution of the arterio-sclerosis as favoring the view that it depends upon increased arterial pressure. Both the ascending aorta and the arch were often found dilated, frequently in a circumscribed aneurysmal form. In some cases rupture had occurred, and in the majority of cases of rupture dissecting aneurysms had formed.

Of the remaining anatomic changes the most important are, hypertrophy of the heart, especially of the left ventricle, and an enormously and well-marked development of the collateral channels between the vessels upon the proximal and distal sides of the narrowed part of the aorta. The vessels which undergo dilatation for the purpose of furnishing collateral circulation are, on the one side the subclavian and axillary arteries and their branches, and on the other side the intercostals, superior epigastric, deep epigastric, and possibly also the phrenic. The blood reaches the lower half of the body by way of three principal routes: 1. Through the abdominal aorta by way of the intercostal arteries; 2, through the superficial epigastric and long thoracic on one side and the deep epigastric on the other; 3, from anastomoses through the intercostal arteries and the ilio-lumbar and circumflex iliac arteries. From the clinical standpoint it may be stated, that stenosis and obliteration of the aorta in childhood produce symptoms in but a small number of cases, and these symptoms resemble as a rule those of congenital heart disease. As a general statement, it is said that from about one to one and a half years before death some acute disease develops and in a comparatively short time the symptoms of incompetency of the heart present themselves and death results from heart failure or some intercurrent disease. The average duration of life of these patients lies between 31 and 32 years, but sixteen reached 40, twelve 50, and one lived to be 92. The principal diagnostic points are: The demonstration of dilated collateral channels; distinct differences in the pulse of those arteries which arise proximal and distal to the stenosis or obliteration, especially the retardation of the pulse in the distal arteries, and third, the disturbance of the heart's action.

Finally, the author presents a quite complete summary of the theories which have been advanced to explain the pathogenesis of the changes under consideration. He concludes that the different theories show very well how little in reality is known concern-

¹ Om stenosis och obliteration af aorta vid eller i närheten af ductus Botalli, Lund, 1898.

ing the final cause of this condition. He therefore calls attention to the fact that at present almost all that can be said is to emphasize the possibility that the aorta, in a certain percentage of individuals, becomes narrowed on account of contraction of newly formed connective tissue in the wall, and that this formation of new connective tissue develops because the proliferation which leads to the obliteration of the ductus Botalli extends into the walls of the aorta. As regards the case which the author examined microscopically he assumes that the stenosis in this instance developed from some congenital abnormality in the arrangement of the various structures of the artery.

THE RATION OF THE VOLUNTEER SOLDIER.

Last week we referred to some of the difficulties experienced by the Army Medical Department in organizing for field service. Today we purpose discussing the causes which have brought the Subsistence Department of the Army under criticism, because if our medical brethren in the field have a correct understanding of these causes they can do much to remove them and promote the comfort and well-being of the men in their commands.

According to newspaper reports from the various camps of our Volunteer Army many of the regiments are suffering from want of food: and acting on these reports the good people of the home localities have expressed groceries by the carload to supplement the reported insufficiency of the Army ration, while the Government has been criticised severely for its failure to provide needful subsistence to the men who have volunteered to fight their country's battles. Besides this, the belief is generally prevalent that the army ration consists essentially of hard bread, bacon and coffee, and that, as fixed by law or regulations, it does not vary amid the snows of Alaska or on the sands of the Gulf Coast. Medical men, and particularly those interested in food and dietaries and in the current work of the Agricultural Department, as published in bulletins from the office of its experiment stations, find a difficulty in believing this, as it implies an ignorance of the first principles of dietetics on the part of those who are charged with the duty of providing subsistence for the Army. Nevertheless, we understand that enthusiastic students of the physiology of food have been so far misled by current reports as to volunteer to set the Department straight on this subject, by calculating for it the calorific value of certain rations, by showing which are the dietaries suitable for soldiers in a tropical climate, and above all by explaining the absolute necessity for a vegetable constituent, to prevent deterioration of physique by an insidiously developed scorbutic taint. A little consideration given to the condition of our Regular Army during the past twenty or thirty years should have demonstrated to these enthusiasts that the army ration is an efficient

ration, irrespective of any question as to the proper appreciation by our subsistence officers of the subjects of calories, hydrocarbons, carbohydrates, albuminoids and antiscorbutics, for where can be found a heartier and better fed set of men than is to be found in the companies of any regiment of the Regular Army of the United States?

The army ration, and by ration is meant the daily regulation allowance of food for one soldier, does indeed consist of a prescribed quantity of certain specified articles of food, but the soldier is not understood in every instance to eat it. If he does not use it he is credited with its market value. The men mess by companies, and if a company does not use the whole of the hard bread, bacon, coffee, etc., to which it is entitled, the money value of the unused parts of the ration is available for the purchase of articles to vary the diet. And that the full purchasing power of this money may be obtained by the company, the Subsistence Department keeps on hand, for sale at wholesale prices, most of the articles of food that are to be found in our city grocery stores. At the present time, the subsistence officer of each of our large camps has on hand an ample supply, not only of the staples of the regulation ration, but of the articles which may be purchased in place of them. No complaint of a deficient dietary has come from any of the regular regiments, although they are subject to the same ration and regulation as the Volunteers; yet from the latter come so many complaints of the inadequacy of the governmental ration that the representatives in Congress of various regiments have appealed to the War Department for a change in the methods. This has led, at Camp Alger, near Washington, D. C., to the issuance of a circular by the Chief Subsistence Officer of the 2nd Army Corps:

"It having been reported at these headquarters that certain regiments of this command have received no fresh beef or fresh bread, the attention of officers on duty as commissaries of the various regiments is called to the fact that there is to be found absolutely no excuse for this condition of affairs. Fresh beef, fresh bread and fresh vegetables are and have been issued regularly by the depot commissary at Dunn Loring station to every regiment making proper requisition therefor, and if any regiment has not received them the fault and the remedy are to be found in its own officers.

"Commissaries are reminded that it is their duty not merely to receive such supplies as may be furnished them, but to see that the men of their organizations receive to the full extent all to which they are entitled. And the fact that any regiment in this command, with ample supplies and facilities for distribution now at hand, should day after day be deprived of proper food, implies a clear neglect of duty on the part of the responsible officer of that regiment."

The Chief Subsistence Officer in this case throws the blame on the regimental commissaries of subsistence; but the duty of the latter is to provide, if possible, what is called for by the companies. It is true each regimental commissary could do a great deal to remedy existing evils by teaching company officers their rights, privileges and duties in this matter; but as a rule he is as ignorant of these as the company officers themselves. The company commander is the

individual responsible for the rationing of his men, to which and the subsequent preparation of the food he is required by Regulations to give as much personal care and consideration as will insure a plentiful and varied diet. Very few of the company officers of our Volunteer Army understand this. They devote their energies to drills and tactical work and leave to "the Government" the duty of supplying their men with food.

As sanitary officers medical officers have a concern in these matters. They are required by Regulations to examine . . . the character and cooking of the food and to make such recommendations as may seem to them to be of value. They have therefore the right to interfere and urge upon officers of the line that proper care be given to the rationing of the men, confident that with such care there would be no more complaint of a deficient dietary.

THE "BUGABOO OF THE MAD DOG."

The fact that there is such a disorder as canine rabies has been so long accepted by the medical profession that the other fact, made rather manifest within a year or two past, that there are some respectable physicians who doubt its existence seems at first sight unreasonable, if not absurd. Certainly the burden of proof lies on those who thus contest one of the established beliefs not only of medicine but of the general public from all time past, and it ought to require more than ordinary evidence to overthrow it. It may be admitted that it is a rare disease of the human species, in this country at least, and that its conventional syndrome is often counterfeited by nervous and hysteric subjects, even to the extent of carrying them to a fatal termination, without the actual infection having ever been in play, but these are by no means conclusive that such infection is a myth and that there is really no such disorder. The existence of a pseudo-rabies does not exclude a genuine form any more than does a pseudo-syphilis, and the mere fact of the comparative rarity of an affection is no argument against its occurrence, when that is attested not only by history and experienced observation but also by scientific control inoculations and other tests. There have been too many cases thoroughly observed and reported to make the skepticism that some profess, appear even reasonable, though it may be allowed as evidence of mental idiosyncrasy that when confined to purely professional discussions is harmless if not altogether admirable. The importance of prophylaxis in this disorder, however, is such, that if such views were likely to be generally adopted mischief might result, and this possibility is the more serious when statements are made in the lay journals by popular writers that there is no such disease as hydrophobia and that the reported cases are "in reality nothing more nor less than instances of people who have been

bitten by dogs and frightened into hysteric conditions in which they involuntarily reproduce all the supposed symptoms of hydrophobia," that the public, and especially the nervous and impressible portion of it, "should believe that there is no such thing as 'hydrophobia'" and rid themselves of the "bugaboo of the mad dog." There is perhaps not much probability of the popular faith in the existence of this disorder being destroyed, but it is more than questionable whether, on hygienic grounds, the medical profession ought to let such misleading statements go unheeded. Certainly they should not if they are accepted by any considerable portion of the public and acted upon accordingly. Such a course would very possibly cure itself in time by furnishing some indubitable examples of the disease that would have been avoided under the ordinary conditions and the heretofore accepted popular beliefs, but this is not a desirable outcome, of itself, and would be better avoided. The fact that the disease is rare in man, in this country, is largely due to the popular apprehension, and the precautions thus induced. It gives rise no doubt to a slaughter of the innocents that the philozoists may deprecate, but this is probably unavoidable until there shall exist some higher degree of public enlightenment and a more thorough and rational system of sanitary police. If at present a salutary fear of hydrophobia may cause hasty and indiscriminate extirpation of dogs, at certain times, and especially when one of the periodic hydrophobia panics exists, there is still reason to consider the results as not altogether evil. A superabundance of dogs is responsible for other evils than merely those of hydrophobia, and an occasional reduction of their number may be considered as a sanitary measure.

While it may be admitted that rabies, either canine or human, is not so common in this country, this is not the case in some other parts of the world. In Russia it is said to be much more frequent and the Eskimos know it and dread it and consider a winter distemper which is often very fatal amongst their dogs as a modified form of the disease. PASTEUR analyzed over five hundred authentic cases in France and his authority will not be easily overthrown by those who, working with much more limited data, are so free with their deductions and criticisms, and insinuate, if not openly charge, that well attested and reported cases are simply "laboratory hydrophobia." A single well supported case would be sufficient to riddle the denials of the existence of the disease if not to fully establish its existence, and we have now probably hundreds confirmed by control experiments upon animals in which imagination and hysteria can be absolutely excluded. From a point of view of admissible medical evidence the question would appear to be fairly settled, so far as the present available data are concerned, in favor of the existence of the disease.

So long as an occasional case occurs and is recorded in the public prints it is not likely that the popular belief in the reality of hydrophobia will become altogether extinct, in spite of all that may be said by those who disbelieve. It will be a misfortune, however, if popular writers, who are always ready to take up and vulgarize medical heresies, should succeed in creating any degree of false security that might lessen the necessary precautions against rabies. With such a disorder prophylaxis is a necessity and any error had better be on the safe side.

FOR THE AID AND COMFORT OF SUFFERING SOLDIERS.

To form an opinion from present indications there will be little need during the war with Spain for this country to call for the Red-Cross assistance of other nations through the medium of our membership in the International Society. The American National Red-Cross, Miss CLARA BARTON, President, has, we understand, given formal notice to the Departments of State, War and Navy and to the Surgeons-General of the Army and Navy of its readiness to respond to any call for civil aid to supplement the hospital work of the Army and Navy; and in powerful support of this the New York Red Cross Relief Committee has given official notice that it stands ready to furnish all necessary money and material to carry on the work. The American National Red Cross is thus ready if called upon not only to give aid and comfort to suffering soldiers in the general hospitals but to reinforce the Medical Department of the Army with volunteer nurses and supplies on the field of battle.

It seems, however, as if the resources of the Government and the patriotism of individuals and associations outside of the National Red Cross would render unnecessary any participation by the latter in hospital or field work. The organization of a special hospital corps, which the Army did not have during the last war, enables the Medical Department at the present time to care for the wounded on the field without volunteer assistance; and appropriations by Congress have provided for all the essential requirements of the general hospitals. There remains to be supplied to the latter only such articles as must be regarded in the light of delicacies or luxuries, and these the patriotism of the country appears to be forcing upon the Medical Department without waiting for any official call in this regard. War had hardly been declared when a National Relief Commission was organized in Philadelphia and propositions relating to organizing for relief work were heard in Illinois, in New York and many other States. So many inquiries were made by Chapters of the Daughters of the American Revolution Departments of the Woman's Relief Corps of the Grand Army and by individuals in various parts of the country concerning the supplies that would be most acceptable that Surgeon-

General STERNBERG had to publish a memorandum to be used as a reply. This opened the way and since then money and supplies have been received not only by the general hospitals but by field division hospitals. Among the larger checks received was one for \$1000 from the National Society of the Colonial Dames of America, for the use of the hospital at Key West, Florida, and a second for \$500 for use elsewhere; the Colonial Dames of New York sent \$500 for the use of the Hospital Ship *Relief*.

Thus for the present and the immediate future the competency of the legalized organization of the Army Medical Department and these voluntary offerings obviate any need for formal assistance from the American National Red Cross; but, should the war be protracted and exhausting, organized assistance such as may be available under its auspices will be of great value to the sick and wounded.

DELAY IN PUBLICATION OF MINUTES.

We extremely regret that we have not been able to obtain the resolutions adopted at the Meeting from the Secretary of the Business Committee, Doctor BULKLEY, up to this time; consequently the ASSOCIATION must wait the convenience of Doctor BULKLEY before the complete minutes can be produced. The only person however to whom the JOURNAL can look for official papers is the Permanent Secretary. If that officer allows important resolutions to leave his hands, he must take the responsibility. He should see to it that the intense desire of the Business Committee to conduct the affairs of the ASSOCIATION, does not lead its managers to suppress the minutes altogether. For the first time since the JOURNAL was founded, the proceedings have failed to be printed in the current volume.

CORRESPONDENCE.

WAR CORRESPONDENCE.

BY LIEUT.-COL. NICHOLAS SENN, U.S. VOLS.,

CHIEF SURGEON SIXTH ARMY CORPS.

CHICKAMAUGA, June 3, 1898.

Chickamauga! What a terrible name to the reunited nation! Here was enacted one of the bloodiest dramas in American history. It is here where one of the most desperate battles of the War of the Rebellion was fought. Almost every foot of soil of this great National Park was stained with the blood of heroes on both sides. What a grand spectacle this beautiful park must have presented when it was the scene of one of the greatest battles known to history! Two great armies composed of the same flesh and blood, face to face, engaged in a deadly conflict. Upon the issue depended much on both sides, hence the heroism displayed and the terrible sacrifice of life. It seems to me I can hear now the beat of the drum, the shrill voice of the fife, the thundering roar of cannon, the rattle of musketry, the shouts of command, the groans of the wounded and the labored breathing of the dying. The bullet-riddled trees, the innumerable cannon occupying the same position as when they vomited forth fire, death and destruction, the many beautiful monuments and tablets commemorating the position of troops during action, and the places where distinguished leaders fell,

are the silent witnesses of those awful days when our Nation was threatened by disruption and even death. It was no fault of our valiant enemy that the star spangled banner triumphed. The victory was dearly bought. Thousands of brave soldiers are resting in yonder cemetery. Many wounds inflicted still remain. Many an aged mother and father have had their life saddened by an irreparable loss sustained in that battle. Many an empty chair has remained in numerous lonely households. It will take more than another generation to wipe out the immediate consequences of the horrors of that battle. Let the present and all coming generations remember with veneration and true gratitude the heroic deeds enacted here. Years have gone by and this great park has become again the camping ground of a large army. Within a few weeks nearly fifty thousand men have pitched their tents and are making active preparations for war. The hills, fields, woods and ravines are swarming with soldiers. Mounted officers are galloping in all directions in clouds of dust. Brigades, regiments, companies and squads are hard at drill under the burning sun. Sentries are stationed everywhere to preserve order, protect property and learn the art of watch dogs to protect the troops during the active campaign along the coast and in distant islands, the the prospective fields of warfare. Almost every day new regi-

somewhat undulating and is cut up here and there by ravines, which add much to the beauty of the scenery. An ample supply of pure water is obtained from numerous wells, from 15 to 65 feet in depth, recently supplemented by a pumping station which derives the water from the river, a short distance below Crawfish Springs, and distributes the water to different parts of the park through iron pipes. The vastness of the grounds are realized by the visitor as soon as he reaches George H. Thomas camp, which at the present time is occupied by nearly 50,000 men, and yet seldom more than one regiment can be seen at one and the same time. In the past, Chickamauga has had an unenviable reputation as a health resort. The Indian name Chickamauga signifies literally "River of death." Along the banks of the Chickamauga river, which flows through the park, malaria was very prevalent years ago, which probably had something to do in inducing the Indians to designate this river by such a terrifying name. At the present time malaria has nearly disappeared from this part of the country, except a very localized district north of Crawfish Springs. The malaria contracted in this circumscribed locality has been of a mild form and is probably due to the draining of a little pond on the south side of Park Hotel.

An adequate number of sinks from four to eight feet in

LEITER HOSPITAL, CHICKAMAUGA, GA.

ments arrive from every part of the country, often without arms and uniforms, but eager and ready to be instructed in the art of war. Our patriotic citizen soldiers in civilian dress envy their more fortunate comrades in showy blue, and impatiently await their turn to don the soldier's garb. It is refreshing and interesting to observe what patriotism will do in antagonizing the imperfections and hardships of camp life. Do you imagine you could hire many of these soldiers to do ordinary work under similar conditions at \$5 per day? No! Give them a uniform, a gun, and an opportunity to fight for the honor of their country and the glorious stars and stripes, and they rush to the front without a word of complaint, unconscious of the privations and hardships incident to the life of the soldier.

SANITARY CONDITIONS.

Chickamauga Park is admirably adapted for a large camp. It embraces several square miles. The forest trees furnish protection against the burning rays of the semitropical sun and the many open places and fields are utilized as drill grounds. Humus is scanty and the subsoil is of clay. The surface is

depth have been dug a safe distance from tents and field hospitals, all of which are boarded in. Three times a day the deposits in the sinks are covered with dry earth and ashes from the stoves and camp fires. One of the difficulties so constantly prevailing in camps has been the introduction of harmful articles of diet by interested friends and enterprising merchants. The regulations governing this evil are becoming more and more stringent and are more effectively carried out, so that the danger from this source is diminishing progressively.

PREVAILING CAMP DISEASES.

The most common disease affecting the troops at this time is diarrhea. The continuous heat, the change and often imprudence in diet and sleeping on the ground are the most important etiologic elements. The last mentioned cause becomes apparent from the fact that the privates are much more frequently affected proportionately than the commissioned officers, most of whom enjoy the luxury of a cot. A number of deaths have occurred from cerebro spinal meningitis, more especially among the Illinois troops. In my first communication I traced the disease to Camp Tanner, where it originated from a case

brought there by the first regiment of cavalry. A few days ago Capt. Lemke, 3rd Regiment Illinois Volunteers, made a postmortem examination at the 1st Division Hospital, 1st Army Corps, which demonstrated the pathological appearances of the disease to perfection. There was a difference of opinion in reference to the location and nature of the disease, as during the early history of the case the symptoms referable to the cerebro-spinal centers were conspicuous, while later a complicating pneumonia masked the manifestations of the original disease. The examination showed croupous pneumonia involving one lobe of the lung, of recent origin, while the meninges of the brain and spinal cord presented all the evidences of an acute inflammation. The lining membranes of all the ventricles were involved. The pathological changes were most marked at the base of the brain and more especially the pons Varolii and medulla oblongata. In these localities the meninges were found infiltrated and covered with a plastic exudate.

The remaining portions of the membranes enveloping the brain and cord were extremely vascular and in some places presented an opalescent appearance. A considerable quantity of turbid serum was found in the ventricles and subarachnoid space. It was evident from the postmortem appearances that

tracted before the patients reached the camp. Considering the inadequate clothing of many of the volunteers, the heavy dew and the chilliness experienced some nights, it is remarkable that so few suffer from rheumatism and bronchitis. Sunstroke and heat exhaustion have so far not visited the camp, although heavy marching and active drilling often take place with the sun high up in the horizon. On the whole the health of the troops is excellent.

A TIMELY BENEFACTRESS.

As soon as I arrived at Camp George H. Thomas I called on Lieut. Col. Harteuff, U. S. A., who received me very kindly and spent nearly half a day in showing me the location of regiments and field hospitals. His experience since he took charge of the medical affairs of the camp had taught him that the hospital facilities even with the limited number of sick at the present time were entirely inadequate. Near the park and on the south side of it, adjacent to the famous Crawford Springs is a large well built hotel containing seventy rooms, which had recently been evacuated and on which he had an option for a few days, purchase price \$10,000. The building alone cost \$65,000 and as the purchase price included the entire furniture, water privilege and four acres of land, and the building

CRAWFISH SPRINGS AND LEITER HOSPITAL.

the primary disease involved the nervous centers and that the lobar pneumonia set in later as a complication and contributed toward an early fatal termination. Two cases of cerebro-spinal meningitis, presenting grave symptoms observed in Camp Tanner, improved promptly after lumbar puncture and I have been subsequently informed that both of these cases ultimately recovered. The first tapping was made by Lieut. Rowe of the 1st Illinois Cavalry. All cases of cerebro-spinal meningitis that have been sent to the Division Hospital have been placed in isolation tents for the purpose of preventing further spread of the disease. Measles has broken out in the camp and all patients suffering from this disease, about twenty in number, at the present time are under guard in isolation tents. The disease is mild in type, the patients as a rule being confined to bed not longer than four or five days. Pneumonia has been prevalent, especially among the regiments from the northern States. Delirium is usually absent although the disease otherwise has assumed a grave type. In several fatal cases the postmortem changes indicated that death resulted from secondary streptococcus infection. At the present time there are only three or four cases of typhoid fever in camp and in most of them it is more than probable that the disease was con-

was in a condition that it could be occupied at once without much repair he had strongly recommended its purchase for hospital purposes to the Surgeon-General. There was no question as to the desirability of acquiring the property to better and increase the hospital facilities; neither could there be any doubt of the government's willingness to buy it to meet the existing emergency, but past experience satisfied all concerned that it would take weeks, and perhaps months, before the building could be made available by relying on the routine way in acquiring the property. Recognizing the necessity for immediate action in the premises and the fact that the option was open only for a few days, at the expiration of which the owners intended to reopen the hotel, I asked permission of Col. Harteuff to allow me to make an attempt to secure the building by donation and later present it to the Government. This request was willingly granted. I telegraphed to Mrs. L. Z. Leiter, Washington, D. C., the condition of affairs and in due time received the pleasing information by wire from her husband that I should proceed at once and draw on him for the amount. After overcoming some of the technical difficulties in the way of securing the necessary water-supply from the adjacent Crawford Springs, the purchase was made and the

"Leiter Hospital" has become a beautiful monument to the memory of a distinguished family that has given the first large donation for the benefit of our sick citizen soldiers at the very beginning of the Spanish-American war. May this noble example find many imitators!

Medical Missionary Work in China.

SIoux CITY, IOWA, June 13, 1898.

To the Editor:—I am advised by Dr. Senn, Chief Surgeon of the Sixth Army Corps, to bring to your notice a needy case in the hope of securing aid.

Dr. I. J. Atwood of Fen Cho fu, China, a graduate of Rush Medical College, has established a hospital, dispensary and opium refuge as a part of his mission work in Fen Cho fu, where much good work has been done in spite of inadequate room and poor equipment. I might tell of many interesting cases which have come under his care.

He has, at last, succeeded in overcoming Chinese prejudice against amputation, but please read the enclosed extract from a recent letter of his and learn the difficulties with which he has to contend.

Is there not some surgeon among your readers who has a second best case of surgical instruments he would like to donate to the hospital?

Dr. Atwood's work is under the American Board of Foreign Missions.

Hoping to secure the interest of your readers and the instruments so much needed in Fen Cho fu Hospital,

I am very sincerely yours,

MARY A. ATWOOD.

P. S.—The address of Dr. I. J. Atwood is Tientsin, China.

EXTRACT FROM A LETTER FROM DR. I. J. ATWOOD A MEDICAL MISSIONARY IN FEN CHO FU, CHINA.

The work of the opium refuge and hospital has been going on as usual, and most of the converts have come in through these channels. One man and his wife have just been taken in. She came into the hospital in a most wretched condition, opium and microbes had done all they could for her. Her bedding was one mat of slime and filth; her face as black as a coal-heaver's; her skin was wrinkled and the cords and veins stood out like whip-cords on her bony, almost skeleton body, while a child of two years old clung to her skinny breasts, trying to get sustenance. To complete her misery, a cancer extending to the bone on either side of one foot kept her from sleeping nights with excruciating pain. The first thing to do was to leave off opium, and if the "torments of the damned" are any worse than what she suffered, they are indeed indescribable. She would sit upright and sew all night long, to make the night tolerable. In this she showed great determination. When the opium chains were loose the poor body was built up with Mellin's food and milk. Then came the ordeal of amputating the leg just below the knee, for the cancer was spreading, and was more painful than ever since the opium was gotten rid of. *The station does not possess an amputating case*, so a saw was made of a piece of band-iron from one of our Boston boxes, with a frame to hold it, and with this saw and a finger knife the leg was amputated. She did well in spite of microbes, and now her face is round and healthy, and so is that of her child, for the milk returned, and the family is happy. They were both very attentive to the Truth, and have accepted it gladly, and have asked to be taken into the church. Their names were taken on probation.

Well, we have gone over another Chinese new year, and are cleaning out the hospital and refuge for a new lot. They will soon be on hand in increasing numbers. Sunday, while we were at meeting, a boy about 14 years old was brought in with one femur broken in four pieces! He had fallen off the city wall, where it is the custom to go on the 15th or 16th day of

the new year to escape sickness for a year! It is supposed that a stroll on top of the city wall at that time will so attract the propitious influences that one may get immunity from diseases for a year.

Epidemic of Tonsillitis.

HOGANSVILLE, GA., May, 1898.

To the Editor:—An epidemic of tonsillitis appeared in our village and vicinity, July 1, terminating Dec. 1, 1897.

Case 1.—Roy P., white, age nine years. Upon examination I found both tonsils congested, and the size of a full-grown almond; tongue thickly covered with a lemon-colored fur, from the base to the tip. On the second day, on left tonsil, one ulcer one-fourth of an inch in length, from above downward, by one-eighth of an inch in width antero posteriorly, made its appearance notwithstanding the use of strong astringents locally as a gargle, and the internal administration of mild mercurous chlorid in one-quarter grain doses every hour until six grains had been given; cauterized with molded nitrate of silver. The third day a similar ulcer formed upon the right tonsil; treatment was the same, with nitrate of silver. The fourth day both ulcers were covered with thin, tenacious white mucus, which was removed, applying the nitrate of silver freely to the ulcer and tonsils, followed twenty-four hours later with a mild astringent gargle.

Not at any period during the attack did the temperature rise above 102 degrees. Recovery was rapid.

During the five months sixty-five cases were under treatment of both sexes, white and negroes, of all ages between three and fifty years, two-thirds of whom were white. All recovered except one white child, a female, six years old, whose death was caused by hemorrhage from the left tonsil eloughing away completely on the ninth day.

A peculiarity of the epidemic was that all children in the families were attacked, except infants under one year, who proved to be immunes, as none were isolated, one infant of three months remaining continually in the room, day and night with her sister, the case that terminated fatally.

R. H. JENKINS, M.D.

Popular Physiology.

RYAN, IOWA, June 17, 1898.

To the Editor:—The following clipping from the Lincoln (Neb.) *Journal* is a rather peculiar specimen of popular physiology:

"The windpipe was partially severed, and the sufferer could only breathe by dropping his chin close to his throat. Otherwise the air escaped through the gash instead of going into the lungs."

Sincerely yours,

A. H. SCOFIELD, M.D.

ASSOCIATION NEWS.

American Medical Association.

Official Minutes of the General Sessions of the Forty-ninth Annual Meeting, held in Denver, Colo.,

June 7, 8, 9 and 10, 1898.

JUNE 7—FIRST GENERAL SESSION.

The Association met in the Broadway Theater at 10:30 o'clock A.M., and was called to order in the absence of President Sternberg, by the First Vice-president, Dr. Joseph M. Mathews of Louisville, Ky.

Dr. Mathews, in calling the Convention to order, said: Before opening the session I desire to read the following telegram which I have just received:

"Joseph M. Mathews, First Vice president, American Medical Association:—Please convey to the Association my best wishes for the success of the Denver meeting, and my sincere regret that important official duties prevent me from being present, and express my heartfelt acknowledgement for the honor conferred in electing me President.

[Signed]

"STERNBERG, Surgeon-General."

The message was greeted with applause.

Prayer was then offered by Chancellor W. F. McDowell of Denver.

At the conclusion of the prayer, Dr. R. Harvey Reed of Wyoming made the following motion:

In view of the telegram just received from our distinguished President, I move that our distinguished Vice-president, Dr. Mathews of Kentucky, be made President *de facto* of this meeting. Seconded.

Dr. J. N. McCormack—I rise to a point of order.

The President—Please, state your point of order.

Dr. McCormack—The President of this Association, Surgeon-general Sternberg, has not resigned his position. He is unavoidably absent on account of imperative official duties, and I do not think this motion is in order. I therefore ask a ruling from the Chair relative to this matter.

The President—I declare the motion out of order. (Applause.)

The President then introduced the Chairman of the Committee of Arrangements, Dr. J. W. Graham of Deuver, who made the following remarks:

REMARKS BY DR. GRAHAM.

Dr. Graham was warmly received. He said: "Words fail to express the joy of our hearts today in greeting you one and all to our beloved city and State. We feel greatly honored that the beginning of the new half of the century in the existence of this distinguished body should begin its labors in our city of the West. It is our hope concerning the members who are passing and have passed away, the great men of this organization, that the mantle of their great power will fall on you, so that you may take up their labors and begin in our city a newer work, a greater work, that shall justify the expectations of the time, place and the age. We desire to see inaugurated in this city today the beginning of that movement which will place the medical profession where it belongs in the city of Washington. We desire to see a department of public health recognized in the cabinet of the President of the United States (applause), and we expect you to take such action today as will request and, if needs be, compel that that be done ere we meet again. (Applause.)

"In behalf of the physicians of the city of Denver and of the State of Colorado, I extend to you a most hearty welcome.

"I desire on behalf of the profession of the State to present to you at this time our distinguished Governor, the Honorable Alva Adams." (Applause.)

ADDRESS OF WELCOME BY THE GOVERNOR OF COLORADO.

Governor Adams was greeted with great applause. He spoke as follows: "Mr. Chairman, Ladies and Gentlemen: There is no convention that is more welcome to Colorado than that which is now assembled here. Profit is always a guarantee of sincerity, and by that standard you will know that in our words of greeting there is no insincerity or falsehood. We welcome you for the friendship we hold for you as an Association, and as individuals; but there is incidentally a profit and a gain that come to Colorado. Notwithstanding the vagaries and peculiarities of our climate during the last few days, I still insist that our climate is our greatest resource. (Applause.) It is of superior quality, and, as you know, infinite in variety. (Laughter.) And then we have it in unlimited quantities. It extends several hundred miles north and south, east and west, while above it is bounded only by the sunshine and the empyreum of God's heavens. While we have this climate to sell, we recognize that there are no better agents to exploit it and advertise it than the fifteen hundred intelligent physicians of America assembled here today. (Applause.) There is, however, an element of business reciprocity between you and us. While we gain through the endorsement of the doctor, we give him an asylum where he can send his hopeless and chronics. You know in the days of Shakespeare, when doctors knew not what to do, they ordered their patients to go to court so the king could touch them *à la Schlatter*. (Laughter.) Now the wise physician sends such cases to Colorado. As evidence of the curative qualities of our climate we call your attention to the thousands who come here and who are today walking the streets of our cities, strong, in vigor and in health, in every vocation of life, doing for God and man, and we may state incidentally that as you ride about our city you will note that the most magnificent residences and the finest business blocks are owned by Colorado doctors. (Laughter.) My friends, these palaces and these blocks were built out of Colorado climate. (Laughter.) Our doctors have become self appointed agents for the collection of all royalty due to climatic cures. If you will read the prescriptions which they give out to those whom you send to us, and upon which they make fame and fortune, you will find that these prescriptions can be resolved into 90 per cent. climate, 5 per cent. aqua

pura and 5 per cent. of faith and other ingredients. (Laughter.) But, my friends, aside from this incidental profit which Colorado derives from such a band of advisers as you are and must be for us, we are glad to see you as individuals, as citizens, because when physicians put aside their vocation, there is no class of men that so fitly conforms to the idea and the description of a jolly good fellow, or as royal a friend, or as fascinating and attractive as our doctors. (Applause.)

"I never could understand why Voltaire recommended the devil to beware of any acquaintance with medical men, unless he thought that his Satanic majesty was wasting his time trying to win such pure and incorruptible men. (Laughter.)

"In ancient India only the most noble of Brahmins was allowed to practice medicine. As we read the splendid faces of those who compose this Congress we can half believe that the influence of the ancient law has not been lost. Royal or not, I have always admired the regal way in which doctors ignore their own advice and rule. As I came upon the platform your secretary, Dr. Atkinson, said to me, 'Treat this audience kindly, but do not take their medicine.' (Laughter.) We know that preachers sometimes obey their own injunctions, as, for instance, like Chancellor McDowell here, but doctors never. (Laughter.) Go into their homes, you run against no rules of diet, meals, beverage, sleep; all is liberty and happiness. Perhaps they read with a clearer vision that brief but suggestive Biblical obituary, 'Asa trusted the physicians and he slept with his fathers.' (Laughter.)

"I have a book on biography and in it I noticed the record of one Dr. Wise. It says of him that he died at the age of 30 with dyspepsia. He was a noted and very learned physician, as well as the author of a valuable work entitled 'The Art of Living to an Old Age.' (Laughter.) The giant of all our physicians of Colorado was a man (Dr. Bancroft) who wrote a book to prove that no man could get fat in the Colorado climate, but we stand today upon the dawn almost of the twentieth century and progress is the watchword of the last decade of this dying century, and in no line of human effort is the spirit of advancement more manifest than in the allied profession of medicine and surgery. Medicine has done more for science, more for humanity than any other department of human effort. Medicine, so long under the shadow of suspicion and imposture, is now a great art, while surgery is the nearest divine of all human science. Every meeting of your Association reads new records of achievement. So great has been the revolution of surgical knowledge that the skill you possess today would have saved two hundred thousand lives in the Civil War. Due to the attainments of the army surgeon the young man who goes out to battle against Spain does not take one-half the hazzard his father took in the great conflict a generation ago. To operate upon the wounded now as was common then would subject the operator to trial and conviction for manslaughter. (Applause.) In your profession Americans need go to no other land or age, as our own practitioners are the best in the world. In doing good no profession has been more generous. In hospitals the poor receive courteous treatment and skill as great as the richest and most eminent can command. It has been your profession that has stayed contagion upon the borders of our land, and in times of epidemics, in times of agitation, the members of your profession have manifested a heroism and bravery equal to that of Dewey or a Hobson. (Applause.)

"The greatest physicians and surgeons the world has ever known are living today, yet in your literature you cling to the ancient fathers of your faith to typify your profession. As many cities of Greece contended for the birthplace of Esculapius as for Homer. Bronze, marble and plaster busts of Hippocrates, Galen and other ancients decorate our colleges of medicine and surgery, and the office of the modern practitioner: yet by our standard how little they knew. All the wisdom they possessed would not permit them to practice in Colorado or secure a diploma in the poorest medical school in the land. They could not obtain a diploma in a first class college in America. Napoleon said that Baron Larrey, the physician who followed him in his battles, was the greatest, bravest man he ever knew. When an American desires professional services of the highest character he does not have to go to a past age or to any other country, for under the stars and stripes there live today the greatest physicians and surgeons of the world. (Applause.)

"If kindness to misfortune, sacrifice for the poor, be a pass to paradise, I would rather take the chance of many a poor Dr. McClure than stand in the shoes of some of our proud millionaires. (Applause.) But with all of your ability, with all of your generosity, which is equaled only by your skill, I find that the doctors are a modest set of people. Doctors are very tolerant, indulgent and generous, unless called to consult with some one of another school. With my experience in legisla-

tive matters, and in the discussion of legislative bills which had to do with the regulation of practice and the recognition of different schools of medicine, it has given birth to a suspicion that the first fundamental principle of each school is that the others had no business to practice; that they ought to be prohibited or go to jail. Personally, my condition has much to do with my faith in schools and systems. For instance, if I feel lonesome and forsaken: if the newspapers, and politicians, and the disappointed, turn their pens, tongues and scalping knives upon me, just because I was not as wise as they would be in the conduct of my office and in making appointments, then I feel the need of the soothing, sympathetic treatment of the christian scientist or faith cure. (Laughter and applause.) Again, if I am in what you may call the loafing, novel reading degree of invalidism, when it does not hurt very bad, I call in my homeopathic friends. Their remedies seem as pleasant as their gentle touch and manners. (Laughter.) Their dissertations upon the power of atoms are as fascinating and convincing as a chapter from Tyndall or Hugh Miller. But my friends, so strong is the power of ancient usage, so strong is the memory of youth, and the influence of early training, than when I have an ache, when I feel that there is some chance of my account being called to a close, then I send for the old regular calomel doctor, and I want him quick. (Laughter and applause.)

"In conclusion, let me say that as men whose work, study and experience have been coined into victories for the race, who under the banner of an almost inspired science, have fought and won some of the greatest battles ever waged in the cause of humanity, we extend to you our gratitude and our friendship. Our homes, our cities, our State, are yours. Enjoy them as your own as long as you like." (Loud and prolonged applause.)

The President—I have the pleasure of introducing as the next speaker the Honorable W. S. McMurray, the Mayor of Denver, who will welcome the Association on behalf of the city.

ADDRESS BY MAYOR M'MURRAY.

"Mr. Chairman, Ladies and Gentlemen: After the eloquent remarks of our Governor to which you have just listened, it seems almost useless for me to add anything to the well chosen words of welcome which he has addressed to you, and still I feel that on behalf of the city of Denver, whose chief executive I have the honor to be, and within whose confines you are meeting today to hold your convention, I would be derelict in my duty did I not extend to you a word or two of sincere welcome, not only in behalf of the physicians of Denver, but of the physicians and citizens of the entire State of Colorado. (Applause.) We welcome you as individuals, as American citizens, and as physicians. We are glad to have you come and visit with us. Here in almost the center of the continent you come from the Eastern coast, from the sunset gate, and meet here under the shadow of the Rockies in the same country and under the same flag. And we are glad to welcome you as members of a divine profession, and I take especial pleasure in greeting and welcoming you on that account. Having the honor to be the oldest son of a physician, I know something of a physician's life. I had the honor of coming from that well-known Eastern city, from which so many of your representatives are here today. I refer to Philadelphia. We welcome the triumphs of your profession; we welcome the glorious possibilities that lie before your profession in the incoming century, and we know that you are constantly pressing forward and making rapid strides at these annual gatherings from year to year. You devise new plans which shall make the profession more useful, and add to the knowledge of those with whom you come in contact.

"Regarding the mistakes of the weather of the last few days, the matter is fully accounted for by the fact that the chief weather manufacturer in Washington City has been for some time neglecting his work in efforts to furnish the Naval Strategy Board the many things it needs and wants. (Laughter.)

"A word or two regarding our climate. You have heard of the man who came to Colorado with only one lung and that badly diseased. Inside of a year he wrote to his friends that he now had three lungs. (Laughter.) So, as you go through this city and State, you will doubtless meet with many people whom you would not suspect of having had lung trouble judging from their present condition.

"As you see the marvelous resources of this great Western country as you go through this beautiful city and State, you must remember that this city has been born and practically grown to the extent it has during the last forty years. As you gaze upon the vast plains and mountains of this State you will have some idea of the great possibilities of this country. Those of you who come here for the first time realize as you have never done before what a glorious heritage has been given us

in this nation of ours. As you return to your homes, after having transacted your business, you will have a better idea of the people of this city and State, and of the magnitude of our resources and of the grandeur of the nation of which we are only a part. As you are here then today, we extend to you a sincere and heartfelt welcome. We ask you to go through the city; it is yours. Anything we can do for you, call upon us, and anything we can do to make your trip pleasant, ask it of us. If you do not see what you want, ask for it, is the sign you see everywhere. As you go through the city and see its resources here and there, remember that it is only a small part of this State. (Applause.)

"Permit me again to extend to you a hearty welcome. We trust your stay will be pleasant and profitable. We hope you will cultivate new acquaintances and renew old ones. It is our wish that you may be so entranced with your visit to Denver and Colorado that you will feel there is only one place upon the American continent where you can live and be satisfied, and that is under the shadow of the Rockies in this great centennial State." (Loud applause.)

The President We deplore the fact that Surgeon-General Sternberg is not present with us today, but we are to be congratulated on the fact that he has sent his Address, and I will ask Colonel A. A. Woodhull of Denver, to read it.

Colonel Woodhull then read the Address prepared by President Sternberg, which was frequently applauded during its delivery. (See JOURNAL, p. 1373.)

At the conclusion of the Address Dr. J. L. Thompson of Indianapolis, Ind., took the Chair.

Dr. W. S. Huselton of Allegheny, Pa., offered the following resolution:

Resolved, That the following telegram be sent to Surgeon-General Sternberg:

"That while the American Medical Association in session in Denver regrets that circumstances, national in character, prevent his presence, it desires to thank him for the able Address just read to the Convention."

Seconded and unanimously carried.

Dr. Dudley S. Reynolds of Louisville, Ky.—I move, sir, that the Address of the President be referred to a committee of five appointed by the Chair to take such action as the practical suggestions contained therein may seem to require. Seconded.

Dr. H. A. Hare of Philadelphia—I would suggest that the Address be referred to the Executive Committee.

Dr. Reynolds—I will withdraw my motion in favor of the suggestion.

Dr. W. T. Bishop of Harrisburg, Pa.—There is one more suggestion I would like to make, and that is that the Secretary be directed to omit, and the reporters requested to exclude, any mention whatever of that unfortunate motion made at the beginning of the session in regard to the absence of General Sternberg. It was an unfortunate mistake and ought to be dropped.

The President—The resolution offered was declared out of order.

The next thing in order was the report of the Rush Monument Fund, which was read by the Chairman, Dr. A. L. Gihon.

It was moved that the report be received and referred to the Business Committee with the request that the suggestions contained therein be considered and report to the Association before the end of the meeting. Seconded.

[The Secretary of the Business Committee carried away this report.]

Dr. E. F. Ingals of Chicago—There is one inaccuracy in the report with reference to the expenses of the Business Committee, and I hope it will be corrected. The Treasurer is upon the stage, and I have no doubt he can place us right. The members of the Committee were not paid their expenses up to last year, and I do not think they have been paid since. (The Treasurer did not take cognizance of the remarks of Dr. Ingals.)

Dr. H. A. Hare of Philadelphia—I would like to ask whether if we adopt the resolution of Dr. Gihon, it will carry with it the resolution regarding the payment of traveling expenses of the officers of the Rush Monument Fund, or is it a separate motion?

The President—I should think it ought to be a separate motion.

Dr. T. J. Eskridge of Denver—About one year ago when the Association met in Philadelphia, our distinguished friend Dr. J. W. Graham of Denver, assumed that Colorado would raise two thousand dollars toward the Rush Monument Fund. At that time he did not have a single pledge behind him. He came back to Colorado, and at a meeting of our State Society, within three hours, a subscription was started, and we had the entire two thousand dollars pledged. (Applause.) As Chairman of the Local Committee of the Rush Monument Fund, having

started my practice in the same district where Benjamin Rush practiced and where he won fame, I will say that it gives me great pleasure to hand over to the Chairman of the Rush Monument Fund a check for \$2000, with the understanding, if he wishes, that it be placed at 4 per cent. interest in the First National Bank until it is called for. (Applause.)

Dr. E. D. Ferguson of Troy, N. Y.—In order that we may continue to redeem pledges, I wish to hand to Dr. Gihon a check for \$2000, without any conditions whatsoever for the Rush Monument Association, it being the subscription of the New York State Medical Association. (Applause.)

Dr. A. L. Gihon—A few minutes ago I said we had four thousand and some odd dollars. The amount has already been doubled and I have now over eight thousand dollars.

Dr. H. A. Hare of Philadelphia—As Chairman of the Committee of Arrangements of the Philadelphia meeting of the Association, after closing up the business your Committee found that there was a rebate of 10 per cent. from all exhibitors, leaving a balance, after defraying all expenses, of \$200, which we desire to contribute toward the Rush Monument Fund.

Dr. S. C. Gordon of Portland, Me.—I wish to say, Mr. Chairman, that at the last meeting of the Maine Medical Association, a motion was made by me that our Treasurer be authorized to pay to the Rush Monument Fund the small sum of \$100, which Dr. Gihon can have by drawing upon the Treasurer of that Association.

Dr. Wm. H. Humiston of Cleveland, Ohio—As late President of the Ohio State Medical Society, I herewith present a New York draft on the Fourth National Bank for \$336 toward the Rush Monument Fund.

Dr. Miles F. Porter of Fort Wayne, Ind.—In behalf of Indiana, being the Chairman of the Rush Monument Fund, I wish to say that Indiana is not yet ready to make a final report. She pledged you nothing at the last meeting, although it was said that she would try to do her duty. I have secured about five hundred dollars, a check for which I am ready to hand to the Chairman of the Committee, but Indiana wants to do something more.

Dr. George L. Cole of Los Angeles, Cal.—I bring with me on behalf of California a check for \$110, which is given unconditionally by the California State Medical Association in accordance with the resolution adopted by that body.

At the conclusion of Dr. Cole's remarks, the President put the motion to accept the report, and it was carried.

The Permanent Secretary read his report as follows:

REPORT OF PERMANENT SECRETARY.

Gentlemen:—The Secretary would respectfully report that in accordance with the resolution adopted at the last meeting, he issued a circular letter to each State and Territorial medical society, notifying them of the action taken relative to the fund for the Rush Monument, and the desire to raise a fund of \$100,000 for that purpose. Replies were received from several that a special committee had been or would be appointed to take charge of this matter. It is expected that these committees will report at the time the report of the Monument Fund is called for. From the lists furnished by the State and Territorial medical societies, a list of the societies entitled to representation in this Association has been prepared and published in the JOURNAL of the Association. Your Secretary is happy to say that very few changes or additions were found necessary after the report was published.

In accordance with the By-Laws, your Secretary notified all who were in arrears for three years (a list of whom had been furnished him by your Treasurer), and in many instances the arrears were paid. Having been notified by the Secretaries of certain State societies that a number of persons had been registered who were not in any way entitled to membership in this organization, your Secretary informed these gentlemen to that effect and suggested to them how they could become members of an association in affiliation with us. In a number of instances gentlemen took advantage of this suggestion and became members in full fellowship.

{Signed}

W. B. ATKINSON.

On motion, the report was accepted.

Dr. Henry P. Newman of Chicago, the Treasurer of the Association, read his report as follows:

ANNUAL REPORT OF THE TREASURER OF THE AMERICAN MEDICAL ASSOCIATION FOR THE FISCAL YEAR COMMENCING JANUARY 1, 1897, AND ENDING DECEMBER 31, 1897.

In presenting my report it is my privilege to congratulate this Association upon its constantly increasing growth and prosperity. The year which closed January 1, 1898, added 1500 new members, and during the same time we have dropped for non-payment of dues only about seventy-five members,

being a larger net gain in membership than for any previous year. The receipts during the time I have had the honor of being your treasurer have increased from \$12,695.58 in 1894 to \$32,200 in 1897. The balance on hand January 1, was \$14,092.85, with a reserve or sinking fund of \$3,000. As will appear in the Trustee's report, the Association has recently added a valuable press to the equipment of our efficient and prosperous printing and publishing plant. This with the JOURNAL of the AMERICAN MEDICAL ASSOCIATION under its present able management, constitutes a most valuable asset in estimating our possessions, and is a guaranty of increasing prosperity in the future.

H. P. NEWMAN, M.D., in account with the American Medical Association.

1897		RECEIPTS.

Respectfully submitted, HENRY P. NEWMAN, Treasurer.

At the conclusion of the report Dr. E. Rosenthal of Philadelphia, said: In the report of the Treasurer reference was made to certain bills presented by Secretaries of Sections, and I understand these bills were paid. I have a bill of expenses for work done in connection with the Section on Diseases of Children, and I would like to know whether it will be paid. I only wish to ask for information as to whether the expenditures of the different Secretaries of Sections for postage and such things, necessary for the proper fulfillment of such offices, if brought before the Association in due form or in order, will be paid, or whether the Secretaries have to pay their own expenses. This is the question I wish to raise.

Dr. T. J. Happel of Trenton, Tenn.—I move that the report of the Treasurer take the ordinary course; that is, of being referred to the Business Committee, and that the matter referred to by the gentleman from Philadelphia be passed upon. Seconded.

Dr. John B. Hamilton of Chicago—If the Association will permit me, I can answer in a few words the question of the gentleman from Philadelphia. The bills paid and authorized to be paid by the Board of Trustees are for those expenses incurred at and incidental to the meetings, including printing of special programs and the like. The bills declined to be paid by the Board of Trustees were those which included writing of letters, hiring stenographers and work preliminary to the meetings of the Sections. No discrimination is made in the settlement of those bills. (Report was then referred to the Business Committee.)

(To be continued.)

SOCIETY NEWS.

The Harlem Medical Association of New York City held its annual election on June 13, which resulted as follows: President, Philip A. Malleson; vice-president, Henry W. Mooney; secretary, Joseph E. Lumbard; treasurer, Charles A. Clinton; and trustees, David Franklin, Samuel E. Gibbs and Henry J. Wolf.

The Delaware State Medical Society held its 109th annual session in Wilmington, June 14. The following officers were elected: President, B. L. Lewis, Harrington; first vice-president, O. D. Robinson, Georgetown; second vice-president, William H. Hancker, Farnhurst; permanent secretary, Frank Belville, Delaware City; assistant secretary, John Palmer, Jr., Wilmington; treasurer, William C. Pierce, Wilmington; counselors, Francis L. Springer, James H. Wilson, Hiram R. Burton; medical examiners, James H. Wilson, H. R. Burton, J. A. Ellegood, P. W. Tomlinson, D. L. Mustard, Willard Springer, J. T. Massey, L. A. H. Bishop, O. D. Robinson and E. S. Dwight. The next meeting will be held in Wilmington.

New Mexico Medical Society.—The seventeenth annual meeting was held at Las Vegas. The new officers elected were: President, S. D. Swope, Deming; first vice-president, E. B. Shaw, Las Vegas; second vice-president, J. H. Wroth, Albuquerque; third vice-president, Wm. C. Bailey, Hot Springs; secretary, G. A. Wall, Albuquerque; treasurer, C. G. Duncan. The next place of meeting was fixed at Albuquerque, for May, 1899.

NECROLOGY.

JOHN ALBERT LARRABEE, M. D., Professor of Obstetrics and Diseases of Children in the Hospital College of Medicine, Medical Department of the Central University of Kentucky, Louisville, was born at Gorham, Maine, May 17, 1840. He was the son of John Rogers Larrabee, and Martha Cooms Larrabee; grandson of Ephraim Larrabee and Jane Rogers, and great-grandson of Benjamin Larrabee, Jr., and Lydia Bailey, and great-great-grandson of Capt. Benjamin Larrabee and Mary Eilthorpe. The family is further traceable through an illustrious line, back to 1620, when the first historic account of their presence in this country begins. Dr. Larrabee received careful educational training in his youth at Bethel Academy, and at Gorham; subsequently at Bowdoin College, Brunswick,

Maine, where he finally graduated in the Maine Medical School in 1864. Before completing his medical education he went to Washington City, in accordance with the advice of his cousin, Prof. Conant, of New York, and stood an examination for appointment as medical cadet in the United States Army, September, 1862. Of the sixty applicants, Larrabee stood third in the list, fifteen only being selected. The medical cadet, it was intended, should rank between the hospital steward and assistant surgeon. Some confusion having arisen in reference to this new title, it was abandoned, and no other cadets were appointed. He was assigned to duty at Hospital No. 7, Fort McCook, Louisville, entering upon his duties October 20, where he continued until the time arrived to return to Brunswick, where he completed his medical education, graduating with the degree of Doctor of Medicine, with the first honors of his class. He returned to military service at once, and was assigned to duty at Fortress Monroe, and was Surgeon-in-charge of the sick and wounded on the transport steamer, *Atlantic*. At his own request he was subsequently assigned to duty at Taylor Barracks, at Louisville, subsequently becoming assistant medical director of the post. He was married to Harriet Winslow Bulkley, daughter of William Henry Bulkley and Sarah Lee Riggs, March 30, 1865. Subsequently, in May of that year, he resigned his commission in the army, and entered upon his illustrious career as civil practitioner, at Louisville. He was always conspicuous as a member of the local and State medical societies, never failing to contribute something of scientific value at the regular meetings. He was secretary of the Kentucky State Medical Society for several years. He was one of the founders and subsequently president of the Louisville Medico-Chirurgical Society.

When the curators of the Central University of Kentucky undertook, in December, 1873, to establish a medical department, he became one of the members of its faculty, and aided materially in the organization of the school and in establishing its character and reputation as an institution of learning. He was, by far, the most popular, not to say the most gifted teacher in any of the medical schools of Louisville. He always had the happy faculty of discovering just what the student desired and administering, in the course of his instruction, just what the student needed. He was always one of the leaders in determining the policy of the institution. At the annual election in June, 1893, he was chosen president of the joint faculties of medicine and dentistry in the University, a position he filled with creditable distinction, to the hour of his death. So devoted was he in his attachment to the college that he insisted in his last illness, which he well understood must prove fatal, upon having the diplomas printed that he might sign them before his death; and, with heroic courage, he lay propped in bed and with a bold and graceful stroke of the pen affixed his signature to all of the diplomas, with the exception of one, which he signed on the wrong line. This last official act was completed in the afternoon of Wednesday, June 8. That night toxemia became manifest; coma began twenty-four hours later, and death ended the scene on the 12th of June, at his home on Baxter Avenue, in the Highlands, a delightful suburb of Louisville. Dr. Larrabee was a man of rare personal magnetism. He had a full beaming eye and open countenance, and was master of the choicest English. He was always the center of attraction in any company. He held twice the office of president of the Section on Diseases of Children in the AMERICAN MEDICAL ASSOCIATION. He was frequently the delegate of the faculty to the annual meetings of the Association of American Medical Colleges, in the organization of which he took an active and leading part. He was in thorough sympathy with the movement to advance the standard of medical education, and never relaxed for one moment his efforts to promote the cause. He was the first and only physician to the Home of the Innocents, tendering his

services with devoted interest for more than twenty years. He was, in fact, the founder of the Children's Hospital, in which he took an active and important interest. His opinion in consultation was sought far and wide. He was one of the greatest practitioners of medicine and a pioneer in pediatrics. His clinic on diseases of children at the Hospital College of Medicine was the largest of its kind in this section of the country. Thousands of his students all over the United States unite with his family and immediate colleagues in mourning the loss of a great and good man.

D. S. R.

JOHN BLAIR GIBBS.—Resolutions passed by the Society of the Alumni of Lebanon Hospital, New York, on the death of John Blair Gibbs (*vide* JOURNAL, p. 1481):

WHEREAS, We have learned with profound sorrow and regret of the death of Dr. John Blair Gibbs at Guantanamo, Cuba, we feel that we should express ourselves in a manner whereby his memory may be honored. Not only has a vacancy been made among ourselves which can never be filled, but the medical profession has lost a true brother and the Nation a son whose manliness, noble character and zeal can never be questioned; and

WHEREAS, We have constantly been indebted to him, while acting in the capacity of assistant attending surgeon at Lebanon Hospital, for valuable council and unfailing courtesy, we therefore,

Resolve, That, to perpetuate his name for his heroic conduct, and as a token of our esteem and love, to erect a tablet in the operating room of Lebanon Hospital, and that these resolutions be entered in full in the minutes of the meeting.

F. H. ALLISON, M.D., Kittanning, Pa., June 11, aged 78 years.—P. M. Chadwick, M.D., Omaha, Neb., a graduate of the University of Vermont and the College of Physicians and Surgeons, New York City, June 11.—S. H. Chester, M.D., Jackson, Tenn., June 10.—J. W. Donnell, M.D., Clarkfield, Minn., June 11.—Cyrus K. Kelley, M.D., Plymouth, N. H., June 21, aged 77 years.—Richard W. Mansfield, M.D., Baltimore, Md.—G. W. Miller, M.D., Lampeter, Pa., June 2, aged 68 years.—J. R. Reid, M.D., Thomasville, Ga., June 13.—James H. Stone, M.D., Tappan, Ohio, June 7, aged 67 years, a graduate of Bellevue Hospital Medical College, 1856.—J. B. Cole, M.D., Wabasha, Minn., Ann Arbor, 1881, June 19.

DEATHS ABROAD.—F. Halbertsma, professor of obstetrics and gynecology, Utrecht.—J. L. Alonso, professor of clinic medicine, Salamanca.—F. J. Trier, Copenhagen, one of the most prominent clinicians of Denmark, aged 67 years.

PUBLIC HEALTH.

Yellow Fever Again. Recently seven more cases of yellow fever at McHenry, Miss., were reported to the Louisiana State Board of Health, this being a total of fifteen cases from May 20 to June 13.

Not Liable for Cost of Renovating House.—In the case of Webb vs. the Board of Health of the City of Detroit, a writ of mandamus was prayed for, to compel the board to allow a bill for losses occasioned by a smallpox infection of certain premises, the items charged being: "Cost of renovation, etc., after disinfection, \$107; loss of rent, \$80; furniture, bedding and other articles destroyed, \$40." But the supreme court of Michigan holds, March 28, 1898, that the writ was properly denied. It says that the smallpox broke out through no fault of the health board. As soon as the first case in this house was reported the patient was removed by the board to the hospital and the house quarantined. It was quarantined nearly two weeks when the second case broke out. This patient was not removed to the hospital, but the house was continued to be quarantined by the board. The board did not make a hospital of the house, or make any further use of the goods therein than was necessary to the proper care of the patients, who were there found suffering from the disease. It was the duty of the board to quarantine the house, and for the protection of the public,

to disinfect the premises. For injury to property resulting from a performance of this duty by its officers, the court holds that the municipality was not liable. If, however, the officers did their work negligently and thereby caused unnecessary damage, it is suggested that then the officers were liable, not the municipality.

Militant Prophylaxis of Tuberculosis.—Additional suggestions made since the committee presented their report to the Paris Académie de Médecine include regulations for the proper disinfection of rooms in which persons have died of phthisis, and the cremation of all articles of clothing and bedding among the indigent, to be replaced by the municipality. Laveran urges disinfection of rooms occupied even temporarily by phthisics. He observes that family prophylactic measures may suffice among the well-to-do, but that the only effectual measure for the poor is isolation in a sanitarium or hospital. In spite of the recommendations of pocket cuspidors, visits to twenty of the most frequented drug stores in Paris disclosed that they had never been heard of; absolutely no demand by the profession or public. Out of five dealers in physicians' and surgeons' supplies only one had ever heard of them, and he had sold but three. Professor Landouzy appeals to the profession at large to enter upon a campaign of education of the public, dispelling unfounded fears, but proclaiming the dangers of tuberculous sputa and insisting upon cuspidors in profusion, raised a certain height above the floor. Patients should be instructed at once as to the nature of their malady, which Grancher calls "the most curable of all chronic diseases." He should carry a pocket cuspidor disinfected with the house cuspidors by boiling or with antiseptics every evening. The physician should not wait for certainty, but make a "probability diagnosis" whenever, with loss of strength and emaciation, he notes permanent alteration in the vesicular respiration in one of the pulmonary apices. This militant prophylaxis on the part of physicians will alone accomplish the purpose. A writer in the *Vienna Klin. Rundschau* of May 12 urges that strictly enforced official prophylactic regulations are imperative.

Members of Board can all be Regulars.—One of the provisions of the constitution of the State of Texas is that "the legislature may pass laws prescribing the qualifications of practitioners of medicine in this State, and to punish persons for malpractice, but no preference shall ever be given by law to any school of medicine." This, it was argued, in the case of *Dowdell vs. McBride*, was violated by article 3778 of the Revised Statutes of Texas of 1895, which provides that the "board of medical examiners shall be composed of not less than three practicing physicians of known ability, and who are graduates of some medical college recognized by the AMERICAN MEDICAL ASSOCIATION." But if this be true, and if article 3778 is unconstitutional, Mr. Justice Key, of the court of civil appeals of Texas, suggests the Texas statute regulating the practice of medicine will still be complete, and should be enforced, without reference to that article. And, upon this ground, he expresses the opinion that, regardless of the constitutionality of that article, no recovery should be allowed for medical services rendered by a person who has not complied with the requirements of the balance of the statute. But Mr. Justice Collard, who may really be said to deliver the opinion of the court, in this case, April 13, 1898, states it, as his view, that the provision of the constitution referred to merely forbids that any preference shall ever be given by law to any schools of medicine, in the examination of applicants for certificates before the board, while the board may be composed exclusively of physicians, graduates of schools recognized by the AMERICAN MEDICAL ASSOCIATION, and each member of the association may belong to the regular school, and yet the constitution not be violated. In other words, he maintains that it is only when the

examining board make a preference as to schools of medicine in its action that the constitutional right of the applicant is invaded. He also mentions the fact that article 3638 of the Revised Statutes of 1879, providing that no person, except those who complied with the law, should be permitted to practice medicine, was not carried forward in the statutes of 1895, but was omitted by the codifiers. But, he says, "we think, when the statutes of 1895 are read in connection, the intention becomes clear that the law must be followed, to qualify one to practice medicine in the State, and without such qualification he can not be permitted to practice."

Blindling Contract Made by Board of Health with Physician.—During an epidemic of diphtheria, an arrangement was made with a practicing physician by the board of health of a township that he should take charge of the patients as physician and nurse, and bury the dead, if any; that supplies should be furnished through him; that he should quarantine the houses where there were cases of the disease, and take all necessary steps to check and control the disease. The physician carried out the instructions of the board, and gave nearly all his time to the work. But when his bill, which the board of health allowed and certified, was presented to the board of supervisors of the county, the latter cut it down, because some of the persons treated were able themselves to pay for treatment. Then the physician applied for a writ of mandamus against the board of supervisors. This the circuit court denied, on the ground that it was not the proper remedy, and because it held that services rendered to patients able to pay would not be a charge against the county. But the supreme court of Michigan reverses the lower court on both points, stating that the writ would issue as prayed. It not only justifies this by a citation of authorities, but by stating, April 19, 1898, case of McKillop vs. the Board of Supervisors of Cheboygan County, that if, in emergencies of this kind, it is understood the agreements made by the boards of health can not be enforced, the statutes designed to protect the community in these times, requiring prompt action of the board of health, will be rendered nugatory.

MISCELLANY.

Journal Index.—The complete index, together with title page, etc., for volume xxx of the JOURNAL, will be published next week.

Increase of the Naval Surgical Staff.—A large number of applications for positions as acting assistant surgeons have been received by the Board of Naval Inspectors, at the Naval Hospital at Brooklyn. The bill for the employment of these extra men is still before Congress, and as soon as it becomes a law an examination of the six or seven hundred men who have already applied at the different stations will be held. Unfortunately the bill provides for only twenty-six acting assistant surgeons.

Occupations of 2200 English Insane.—The following is a classified list of some of those who have been admitted into English lunatic asylums during the past five years: Five hundred and seventy-nine agricultural laborers; 484 engineers and artisans; 299 bank, insurance and other clerks; 214 shopkeepers; 213 soldiers; 176 teachers, etc.; 61 commercial travelers; 44 musicians; 30 physicians and surgeons; 28 clergymen; 28 authors and journalists; 22 actors.

New York Professor Resigns.—Dr. James W. McLane, after thirty years of service as a teacher, has resigned the chair of professor of obstetrics in the College of Physicians and Surgeons of New York. In accordance with the wishes of the medical faculty Dr. McLane was made emeritus professor of obstetrics, and retains his position as dean of the college. The vacancy in the chair of obstetrics was filled by the appointment, with the title of lecturer in obstetrics, of Edwin B.

Cragin, M.D. Dr. Cragin is a graduate of Yale, class of 1882, and of the College of Physicians and Surgeons, 1886.

Weakest Kind of Evidence.—The experience of the courts has demonstrated, says Mr. Justice Follett, in delivering the opinion of the fourth appellate division of the supreme court of New York, in the late case of Dobie vs. Armstrong, that the answers of experts, though honestly given, to hypothetical questions embracing pages of assumed and isolated facts covering a long lifetime, about which facts the experts have no personal knowledge, are the weakest and most unreliable kind of evidence in respect to the sanity or insanity of the person inquired about.

Bacillus of Syphilis.—As already mentioned, Van Niessen of Wiesbaden claims to have discovered a polymorphous bacillus requiring only an enlargement of 60 diameters to be visible, resembling the hyphomycetes, in the blood of syphilitics at all stages of the disease, even the most remote from the date of infection. He deduces that syphilis is a chronic disease of the blood, absolutely incurable by all methods known to date and contagious and inheritable at all periods. His detailed communication is published in the *Cbl. f. Bakt. u. Inf.*, Nos. 2 to 7.

The Army in Transports.—On inquiry at the office of the Surgeon-General it was found that the latest medical news from the Fifth Army Corps, General Shafter's command of regular troops, consisted of a report by Lieut.-Colonel B. F. Pope, Chief Surgeon of the Corps. The report was dated June 13, on board Transport No. 12, Tampa Bay, Florida. It stated that the troops embarked on Wednesday, June 7, and had been on shipboard since that date. Eight of the transports were at first considerably overcrowded, but relief had been obtained by unloading 1000 men and putting them on the steamer *Knickerbocker*. In spite of very trying conditions the health of the command was excellent. The steamer *Olivette* had been secured as a hospital ship for the trip, this vessel having been considered better adapted for hospital purposes than any other in the fleet. The medical department is well organized, and according to Dr. Pope "affairs seem to be in good shape for the expedition."

Maryland Hospital for the Insane.—An important step in the general movement for the removal of insane patients from almshouses and jails is that accomplished recently by the transfer from the almshouse of Baltimore of its fifty insane patients to the new State insane hospital near Sykesville. The hospital is a model institution. Its four buildings are constructed pretty much on the same principle as the Johns Hopkins Hospital of Baltimore. There is nothing about it suggestive of a place of confinement. It has no padded cells and no instruments with which to restrain violent patients. Dr. George Rohe, the superintendent, is an advocate of mild treatment. For the accommodation of additional patients when the capacity of the present buildings is exceeded, as is probable in the near future, it is proposed to erect other buildings about half a mile from the present site.—*Charities Review*, April.

Calcutta General Hospital.—A novel feature of the new general hospital for Europeans in Calcutta, India, the corner-stone of which was recently laid, will be a system of ventilation during the hot and rainy seasons by cold and dried air. The idea originated with brigade surgeon Lieutenant-Colonel Crombie, the superintendent of the hospital and, like most new ideas, met with a great deal of opposition, although the advantages of the system are obvious. During the hot and rainy seasons Calcutta has a temperature ranging from 85 to 95 degrees F., and a humidity which frequently reaches 90 per cent. Dr. Crombie proposes to establish a uniform temperature in the wards, of from 75 to 80 degrees F., and a humidity reduced to about 60 per cent., as a necessary part of the process of cooling the air. As a cool dry air is to be passed through screens of cotton wool, there will be no mosquitoes, and accordingly no necessity for punkahs and mosquito curtains.—*Medical News*.

Conservatism in Head Traumatism.—At the Berlin Medical Society, Von Bergmann showed two patients with bullets in the brain. In both, the wounds were healed and the patients presented very few symptoms at the time of demonstration. At first, however, there had been in one case hemiplegia, hemi-anesthesia, one side deafness and total blindness, which had all passed away, leaving finally a slight paralysis only of the left leg. The projectiles were skiagraphed with the X-rays. Notwithstanding the urgent wish of both parents to have the bullets extracted, Von Bergmann had refused to operate, as there was no indication for such interference.

American Medical Missionary Work in India.—In India, where many lethal diseases flourish like plants in a hothouse, and which is a nursery of epidemics and the permanent abode of cholera, it is not unnatural that missionaries should have been led to establish hospitals. The American Board planted a mission in Madura, South India, in 1835, and from the beginning of this mission has devoted much attention to medical relief. Among the doctors who have gone out to Madura as medical missionaries stand the honored names of Steele, Lord and Palmer, the last a brother of Senator Palmer of Illinois. At Dindigul, the veteran Dr. Chester has for thirty-five years devoted his time to this department of missionary work. The medical work carried on by this mission has done much to win the way of the mission into the favor of the native people of that district.—*Harper's Weekly*.

Antitoxin is not "Vaccine Virus."—This is now judicially settled by the decision of the United States circuit court of appeals, in *Koechl vs. United States*, January, 1898. The question arose over the assessment for duty of certain antitoxin, which the collector of customs of the port of New York held dutiable as a "medicinal preparation," while the importers contended that it should be admitted free of duty, as "vaccine virus" under the tariff act of 1894. They cited for this the *Century Dictionary*, which gives as a secondary definition of "vaccine" when used as a noun: "In a general sense the modified virus of any specific disease introduced into the body in inoculation, with a view to prevent or mitigate a threatened attack of that disease, or to confer immunity against subsequent attacks." No authority for this use is cited. The quotation expresses merely the opinion of the compiler or compilers of the dictionary, and the court of appeals goes on to say, more than the mere ipse dixit of a contributor to such a work is required to satisfy it that the words "vaccine virus" are actually used with such meaning by educated people, especially in view of the fact that none of the other standard dictionaries give any such definition of the phrase. So it holds that the collector's classification upheld by the circuit court was correct, while that contended for by the importers and adopted by the board of general appraisers was not.

Convention Notes. Resolutions adopted by the Glenwood excursion party. The members of the AMERICAN MEDICAL ASSOCIATION en route from Colorado Springs to Glenwood on a special excursion train on the Colorado Midland Railway passed a series of resolutions and presented them to George W. Rietine, president of the Colorado Midland Railway, reading as follows, and signed by every member of the party:

"We, the members of the AMERICAN MEDICAL ASSOCIATION, who were fortunate enough to take advantage of the excursion to Glenwood Springs, afforded us in viewing one of nature's greatest panoramas, are especially appreciative of the accommodations, courtesy and kindness shown, not only by the management, but by every employe on the road with whom we have come in contact. We feel that no words of praise we can say in the future for the Colorado Midland Railway can adequately compensate for the pleasure we have derived from the unparalleled trip through the Rocky Mountains."

President Rietine responded, thanking them for their complimentary resolutions, and saying that if the Colorado Midland Railway and its employes have contributed to their pleas-

ure and sojourn in Colorado, they felt repaid for any courtesies extended, and he hoped Colorado would see them again and only regretted that each of them could not take home with him a carload of scenery, as there was plenty to spare.

The ASSOCIATION was represented at Colorado Springs, June 11, by a train load of delegates. Following a luncheon at the Broadmoor Casino and a visit to the Cheyenne Canyons a reception was given by the El Paso Club and a dance at the Mansions with excursions to the summit of Pike's Peak and drives to the Garden of the Gods and other scenic environs.

Many doctors were royally entertained at the Montezuma, Hot Springs, N. M.

The British Medical Staff in the Last Conflict in Northern India.—The following is a comment from a high official source upon the conduct of the medical department of the British forces sent against the Afridis: "Now, I suppose there is no department which has done more admirable work in the late campaign than the medical department, not only in the campaign itself, but also in the treatment of the sick and wounded in the great hospitals that were formed. A large general hospital was opened at a station in the north of India. A newspaper at home published a report affirming that all the arrangements were as bad as they could be, that there was an insufficient staff, that the patients slept on the ground, and that the equipment was defective; that, for example, there were several serious cases of abscess of the liver and only three feeding cups. Now, what are the facts? There was an ample staff: Sixteen medical officers and eighteen assistant surgeons, and some nursing sisters; no patients ever slept on the ground; there were excellent barracks as well as tents; there was an ample supply of every kind of hospital equipment. There was not a single case of abscess of the liver and there were forty feeding cups instead of three; while there was not a single death during the whole of the time the hospital was open. I merely make this statement to show how absolutely ill-founded many of the reports are."

Personal Notes.

NATHAN S. DAVIS, M.D., Dean of Northwestern University Medical School, Chicago, has, owing to his advanced age, resigned that office.

Prof. DANIEL R. BROWER of Rush Medical College has been given the honorary degree of LL.D., by Kenyon College.

Dr. F. C. HOTZ of Chicago has been appointed professor of Ophthalmology, and Dr. FRANK BILLINGS professor of Medicine in Rush Medical College.

Dr. Charles W. Page of the Hospital for the Insane at Danvers, Mass., will enter upon the Superintendency of the Connecticut Hospital for the Insane at Middletown, Conn. He is to succeed Dr. James Olmstead, who died Dec. 4, 1897, and will assume charge about September 1.

San Francisco.

SAN FRANCISCO COUNTY MEDICAL SOCIETY.—At the regular monthly meeting, June 14, Dr. G. W. Davis reported a case of gas asphyxiation. The case recovered; oxygen was not used. Dr. Krotoszyner reported a case of unusual interest, that of primary carcinoma of the pancreas, with no symptoms that in any way pointed to the actual cause of the peculiar trouble. The case was seen by a number of doctors, in consultation, but no one of them was able to give the slightest approximation to a correct diagnosis. On postmortem the liver, lungs and pia mater were found to be involved by secondary growths. Dr. Philip King Brown reported an autopsy that he had just made in a case of hemorrhagic disease of the new-born. The autopsy revealed one new fact, viz.: that the blood would actually clot, for the stomach and intestines were found filled with clotted blood. Several cases of scurvy in infants were reported by Dr. Levison. In one of the cases the true condition was very obscure and the diagnosis of infantile paralysis

had been made by several specialists. The true condition was subsequently made out, and upon the administration of orange juice a cure resulted in about thirty-six hours.

Recent Movements of the Army Medical Staff. Captain John S. Kulp, U. S. Army, has been ordered in from the Department of the Columbia to report to the Surgeon-General for assignment, and Captain W. D. Crosby's orders carry him to the Philippine Islands. Assignments to the 5th Corps, General W. R. Shafter at Tampa, Fla., have been made as follows: Captains Charles F. Kieffer and H. R. Stiles and Lieutenants P. C. Fauntleroy and Carl Darnall, U. S. Army, with Acting Assistant Surgeons Edward C. Posey, J. R. Shaanon, R. P. Strong and Henry E. Wetherill. To General Wheeler's Cavalry Division, also at Tampa, Fla.: Captains Fred P. Reynolds and George J. Newgarden, U. S. Army, and Acting Assistant Surgeon S. M. Gonzalez, while Acting Assistant Surgeon T. S. Dabney has left Tampa for assignment at Jackson Barracks, New Orleans, La. To General Fitzhugh Lee, 7th Army Corps at Jacksonville, Fla.: Acting Assistant Surgeon Geo. B. Lee. To General J. R. Brooke at Chickamauga, Ga.: Captains James D. Gleunan, W. P. Kendall, W. Stephenson and Edgar A. Mearns, U. S. Army. To General William M. Graham, 2d Army Corps at Camp Alger, Falls Church, Va.: Captain A. E. Bradley, U. S. Army. To Major B. D. Taylor at the General Hospital at Fort McPherson, Ga.: Acting Assistant Surgeons Rupert Norton and Ed. Schreiner. To Major George H. Torney on the hospital ship *Relief*, at New York City: Acting Assistant Surgeon Frederick McG. Hartsock. To Major W. R. Hall at the General Hospital at Key West, Fla.: Captain Ogden Rafferty, U. S. Army. Travel performed by the following Acting Assistant Surgeons under the orders of the Surgeon-General has been approved: Samuel T. Armstrong from Washington, D. C., to Key West, Fla.; A. A. Bailey from Richmond, Tex., to Fort Sam Houston, Tex.; Barnard E. Baker from Charleston, S. C., to Key West, Fla.; Frank Roberts from Marshall, N. C., to Fort Caswell, N. C.; J. W. Donnelly from Washington, D. C., to Fort Mott, N. J.; J. E. Miller from Des Moines, Iowa, to Omaha, Neb.; W. E. Parker from New Orleans, La., to Tampa, Fla.; Edward R. Bragg from Ocean Springs, Miss., to Mobile, Ala.; Hamilton P. Jones from New Orleans, La., to Mobile, Ala.; R. N. Pitts from Montgomery, Ala., to Tampa, Fla.; Roger P. Ames from New Orleans, La., to Mobile, Ala.; A. R. Booth from Shreveport, La., to New Orleans, La.; Joseph A. Tabor from Bay St. Louis, Miss., to New Orleans, La.; Thomas Y. Aby from New Orleans, La., to Mobile, Ala.; Irwin E. Bennett from West Philadelphia, Pa., to Fort Delaware, Del.; E. D. Ferguson from Macon, Ga., to Key West, Fla.; and W. B. Winn from Kansas City, Mo., to Mobile, Ala.

Regimental Hospitals in the Second Army Corps.—Chief Surgeon Girard of the Second Army Corps has found opposition on the part of some of his regimental surgeons to the breaking up of their regimental hospitals for the formation of a field division hospital for war service. As it is not to be supposed that the opposition comes from any of the surgeons who have been deemed worthy of a place on the staff of the division hospital, we must suppose that personal feeling enters somewhat into the contention. Colonel Girard's latest circular to his subordinate (?) officers is as follows:

"To the chief surgeons of divisions:

"You will inform the regimental surgeons that the War Department is fully determined on abolishing the regimental hospital system, which has proved a failure, and caused much unnecessary suffering during the civil war, and has been abandoned by all nations which keep their armies prepared for war.

"An evasion or non-compliance with orders on this subject is, therefore, not only prejudicial to good order and military discipline, but unwise and unpatriotic, in pretending to assume a superior knowledge to that of the established authorities, and setting personal views and interests above the common cause.

"You will inform the regimental surgeons, through their brigade surgeons, that the first and second division hospitals are ready for the reception of patients. They are in charge of about one-fourth of the force of volunteer surgeons, and if the

patients do not receive skilful care and treatment no one but the surgeons of the volunteer army will be to blame. To guard against neglect or inexperience, you are directed to send to me a list of names of surgeons, prominent in their profession, in your respective divisions, from whom a consulting board for each division hospital will be chosen. They will be called in consultation in every case of severity, and their decision will be final, subject to my approval.

"You will report to me a list of equipments turned into the division hospitals by the regiments, with a list of regiments contributing.

"You will also report in writing the names of regiments and regimental surgeons having failed to comply with General Graham's orders, in order to enable me to report them to the commanding General."

A New Point of Election for Revaccination.—Dr. Hoggan Ewart writes to the *Lancet* regarding a recent experience in revaccination. He says: "During the epidemic of smallpox at Gloucester, being called upon to revaccinate sixty young women, the inmates of an Anglican Home at Malvern, I revaccinated thirty on the scars left by previous vaccination, and the remainder on the normal skin, and found that the cases revaccinated on the old scars took more perfectly than those done on the normal skin. I also observed that in some of the latter cases, in addition to the reaction arising at the seat of the new abrasions, there was in several cases a sympathetic inflammatory action in one or more of the old scars. Calf lymph was used and there was not a failure in the sixty cases." These remarks run directly counter to the advice of Seaton, who, if we read him correctly where he says of this operation that "it should be done as far as possible from the arm," meaning, no doubt, as far as possible from the site of the primary (or former) vaccination. His instructions in this matter have not their customary clearness and explicitness.

The Reflex of Mr. Gladstone's Career Helpful to Medicine.—It has been frequently observed by writers that Mr. Gladstone had a very limited welcome for medico-sanitary legislation, a view with which the *Philadelphia Medical Journal* does not fully coincide. The editor of that paper, in his issue for June 4, remarks that while the American Press has given some admirable and accurate accounts of that great statesman's career, almost nothing has been brought out to show that the cause of medicine has lost in him a true friend. Mr. Gladstone's remarkable administration of English affairs between the years 1880 and 1885 gave an immense impulse to general education and enlightenment, to liberalism of thought, and to charity of judgment. The profession of medicine shared, to a marked extent, in the rise of the scientific knowledge of the people and in the broadening of their views of life, for Mr. Gladstone's humanitarianism provided in England a political environment, within which sanitary legislation and the practice of preventive therapeutics could best thrive. He was a true friend to man, and used his splendid gifts, always, as he believed, under the direction of his and their Maker, for the advancement of man. Such lives must always help forward the cause of medicine, for those who live them must always be in direct sympathy with everything that is best and noblest in our art.

Cincinnati.

Dr. O. P. HOLT.—At a recent meeting of the faculty of the Miami Medical College, Dr. O. P. Holt was selected to the faculty, vice Dr. Joseph Lieberg resigned.

THE FACULTY OF THE OHIO MEDICAL COLLEGE has undergone some change. Prof. Samuel Nickles resigned his position of the chair of materia medica and was succeeded by Dr. B. K. Rachford; the latter's place, the chair of physiology, was taken by Dr. Poole; Dr. W. H. Crane was elected to Dr. Poole's place, the chair of chemistry. Dr. C. L. Bonifield became professor of clinical gynecology, and Dr. S. C. Ayres professor of ophthalmology and otology.

ORIGINAL RESEARCH SOCIETY.—The members were compli-

mented in the person of Dr. D. I. Wolfstein of this city, whose paper on "The Neuron Theory as Related to Brain and Nervous Diseases in the Light of the most Recent Investigations" was awarded the Fisk Fund Prize of \$350, given by the Rhode Island Medical Society for the best original essay. His article will be published in monograph form at the expense of the Fisk Fund.

CINCINNATI HOSPITAL.—The annual war between the daily press and the Cincinnati Hospital is now on and the former are entertaining their readers with sensational stories of mismanagement on the part of the trustees. The latter have retaliated in their usual manner by excluding reporters from the sacred precincts of the building as though that would accomplish any good result. The Board, in a praiseworthy attempt to cut down expenses, adopted the rule that all medicines should be ordered directly from the drug store and that the ward medicine chests be abolished. The rule became a dead letter as soon as issued, luckily for the Board, or their ears would soon have been assailed with the news of the death of some patient who had died waiting for the medicine that never came, a story the concoction of some enterprising newspaper man. The establishment of war prices in all kinds of hospital materials make it necessary for decided cuts in expenses to be made somewhere, as the hospital appropriation is made on a peace basis.

PUBLIC OFFICES.—When the city started to reform its public offices last year, there was no idea that the powers that be would appoint a health officer other than one satisfactory to the medical profession. But while the latter were sitting supinely around waiting for enthusiastic delegations of politicians to beg them to accept of the position, "Dr." —, a well known advertising medium, did a little solid hustling, and the position was his practically without opposition. Then and then only, when it was too late, did the profession rise in its wrath and declare this thing was not to be, and at the Academy of Medicine a resolution by the city bacteriologist was presented, and after being held over for one week was lost, after considerable heated debate. The resolution was as follows:

Resolved, That it is incompatible with the honor and dignity which such membership carries with it for any member of this society to accept employment under the recently appointed health officer.

As said before, the motion was lost and the following was substituted:

Resolved, That it is the sentiment of this Academy of Medicine that we protest against the appointment of the present health officer as an insult to the medical profession and a danger to the city.

This was carried amid great applause and the measure was of course slurred by the daily presses as a dastardly persecution by the doctors, of an "honorable" gentleman and a good citizen. How much better if all this oratory and vituperation had been exercised to prevent Mr. Tenney from ever getting the office.

HEALTH DEPARTMENT.—Total number of deaths during the month of May, 482: Phthisis pulmonalis, 48; cancer, 23; enterocolitis, 10; gastro enteritis, 11; gastritis, 4; enteritis, 8; convulsions, 11; apoplexy, 16; bronchitis, 33; heart disease, 27; pneumonia, 44; accidental, 17; measles, 89 cases reported, 3 deaths; diphtheria, 21 cases, 2 deaths; scarlet fever, 13 cases, no death; typhoid fever, 16 cases, 8 deaths; phthisis pulmonalis, 50 cases, 48 deaths; membranous croup, 3 cases, 1 death; pertussis, 35 cases, 7 deaths; varicella, 6 cases, no deaths. Of the 89 cases of measles, 25 cases were from one ward and 10 from another; 5 of the 13 cases of scarlet fever were reported from a single ward; 4 of the 6 cases of chicken-pox were from one ward.

THE ACADEMY OF MEDICINE closed for the year June 13, with a paper by Dr. E. P. Adams, entitled "Symphysectomy, with Report of a Case Terminating in Perfect Immobility."

CHANGE OF ADDRESS.
